Graft coronary artery disease (GCAD) is a manifestation of chronic graft rejection that occurs in ≈20% of children 5 yr after transplant. The cause is still unclear, although it is thought to be a form of immunologically mediated vessel injury (chronic rejection). Hypercholesterolemia and hyperglycemia are thought to increase the risk of this disease. Unlike native coronary atherosclerosis, GCAD is a diffuse process with a high degree of distal vessel involvement. Because the transplanted heart has been denervated, patients may not experience symptoms such as angina pectoris during ischemic episodes, and the initial manifestation may be cardiovascular collapse or sudden death. Most centers perform coronary angiography annually to screen for coronary abnormalities; some also perform coronary intravascular ultrasound on adolescents. Standard coronary artery bypass procedures are usually not helpful because of the diffuse nature of the process, although transcatheter stenting can sometimes be effective for isolated lesions. For severe cases, repeat heart transplantation has been the only effective treatment. Thus, prevention has been the focus of most current research. The cell-cycle inhibitors sirolimus and everolimus have been shown to decrease coronary arterial intimal thickening in adult transplant patients. Other drugs that have been shown to reduce the risk of GCAD include the calcium channel blockers (such as diltiazem) and the cholesterol-lowering HMG-CoA (3-hydroxy-3-methyl-coenzyme A) reductase inhibitors (such as pravastatin or atorvastatin).

Other Complications
Corticosteroids usually result in cushingoid facies, steroid acne, and striae. Cyclosporine can cause a subtle change in facial features such as hypertrichosis and gingival hyperplasia. These cosmetic features can be particularly disturbing to adolescents and may be the motivation for noncompliance, one of the leading risks for late morbidity and mortality. Most of these cosmetic complications are dose related and improve as immunosuppressive medications are weaned. Osteoporosis and aseptic necrosis are additional reasons for reducing the steroid dosage as soon as possible. Diabetes and pancreatitis are rare but serious complications.

Rehabilitation
Despite the potential risks of immunosuppression, the prospect for rehabilitation in pediatric heart transplant recipients is excellent. More than 95% of pediatric heart transplant recipients have no functional limitations in their daily lives. The majority of patients do not require rehospitalization for transplant-related problems. Pediatric heart transplant recipients can attend daycare or school and participate in non-collision competitive sports (no tackle football or martial arts) and other age-appropriate activities. Standardized measurements of ventricular function are close to normal. Because the transplanted heart is denervated, the increase in heart rate and cardiac output during exercise is slower in transplant recipients, and maximal heart rate and cardiac output responses are mildly attenuated. These subtle abnormalities are rarely noticeable by the patient.

Growth of the transplanted heart is excellent, although a mild degree of ventricular hypertrophy is commonly seen, even years after transplantation. The sites of atrial and great vessel anastomoses usually grow without the development of obstruction. In neonates who undergo transplantation for hypoplastic left heart syndrome, however, juxtaductal aortic coarctation may recur.

As assessed by standardized testing, the psychologic adjustment to heart transplantation in children is usually good. However, a serious problem with noncompliance often occurs once patients reach
adolescence, and life-threatening rejection may result. Early intervention by social workers, counselors, and psychologists may be able to reduce this risk.

443.2 Heart-Lung and Lung Transplantation

Daniel Bernstein

More than 670 heart-lung and 1,700 lung (single or double) transplants have been performed in children in the United States and Europe, with ≈140 procedures performed annually. Primary indications for heart-lung transplantation include cystic fibrosis, primary pulmonary hypertension, complex congenital heart disease with pulmonary hypoplasia or Eisenmenger syndrome, congenital lung abnormalities, and end-stage parenchymal lung disease (bronchopulmonary dysplasia, chronic lung disease, and interstitial fibrosis). Many of these patients with normal hearts are candidates for single- or double-lung transplantation if right ventricular function is preserved and there has been a trend towards decreasing combined heart-lung transplant for this reason. In some patients with Eisenmenger physiology, double-lung transplantation can be performed in combination with repair of intracardiac defects. Patients with cystic fibrosis are not candidates for single-lung grafts because of the risk of infection from the diseased contralateral lung. Patients are selected according to many of the same criteria as for heart transplant recipients (see Chapter 443.1).

Posttransplant immunosuppression is usually achieved with a triple-drug regimen, combining a calcineurin inhibitor (cyclosporine or tacrolimus) with a white blood cell enzyme inhibitor (mycophenolate or azathioprine) and prednisone. Most patients receive induction therapy with an antithymocyte or anti-T cell preparation. Unlike patients with isolated heart transplants, patients with heart or heart-lung transplants cannot be weaned totally off steroids. Prophylaxis against P. carinii infection is achieved with trimethoprim-sulfamethoxazole or aerosolized pentamidine. Ganciclovir and CMV immune globulin prophylaxis are used as in heart transplant recipients (see Chapter 443.1).

Pulmonary rejection is common in lung or heart-lung transplant recipients, whereas heart rejection is encountered much less often than in patients with isolated heart transplants. Symptoms of lung rejection may include fever and fatigue, although many episodes are minimally symptomatic. Surveillance for rejection is performed by monitoring pulmonary function (forced vital capacity; forced expiratory volume in 1 sec [FEV1]; forced expiratory flow, midexpiratory phase [FEF25–75%]), systemic arterial oxygen tension, and chest roentgenograms and by transbronchial biopsy.

Actuarial survival rates after lung or heart-lung or lung transplantation in children are currently 75% at 1 yr and 50% at 5 yr; improved patient selection and postoperative management are continually improving these survival statistics from prior eras. Graft failure and infection are the leading cause of early death, whereas a form of chronic rejection known as bronchiolitis obliterans accounts for nearly 50% of late mortality. Other causes of early morbidity and mortality include tracheal complications, pulmonary venous obstruction, donor lung dysfunction, bleeding, and acute rejection. Additional late complications include the development of airway stenosis, late graft failure, PTLD, and other side effects of chronic immunosuppression.

Postoperative indices of cardiopulmonary function and exercise capacity show significant improvement. Nearly 90% of patients are without activity limitations at 3 yr follow-up and more than 80% at 5 yr follow-up. Problems of donor availability are even more severe with lung transplantation than with isolated heart transplantation. Living related lung transplantation, in which a lobe from a parent is transplanted into a child, has been used to partially alleviate this problem.

Bibliography
444.1 Kawasaki Disease
Daniel Bernstein

See also Chapter 166.
Aneurysms of the coronary and occasionally the systemic arteries may complicate Kawasaki disease and are the leading cause of morbidity in this disease (Figs. 444-1 and 444-2). Other than in Kawasaki disease, aneurysms are not common in children and occur most frequently in the aorta in association with coarctation of the aorta, patent ductus arteriosus, Ehlers-Danlos type IV (arterial ecchymotic form), hyperimmunoglobulin E syndrome, and Marfan syndrome and in intracranial vessels (see Chapter 601). They may also occur secondary to an infected embolus; infection contiguous to a blood vessel; trauma; congenital abnormalities of vessel structure, especially the medial wall; and arteritis, for example, polyarteritis nodosa, Behçet syndrome, and Takayasu arteritis (see Chapter 167.2).

444.2 Arteriovenous Fistulas
Daniel Bernstein

Arteriovenous fistulas may be limited and small or may be extensive producing systemic complications (see Chapters 505 and 650). The most common sites in infants and children are within the cranium, in the liver, in the lung, in the extremities, and in vessels in or near the thoracic wall. These fistulas, though usually congenital, may follow trauma or be a manifestation of hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease). Femoral arteriovenous fistulas are a rare complication of percutaneous femoral catheterization.

CLINICAL MANIFESTATIONS
Clinical symptoms occur only in association with large arteriovenous communications when arterial blood flows into a low-pressure venous system without the resistance of the capillary bed; local venous pressure is increased, and arterial flow distal to the fistula is decreased. Systemic arterial resistance falls because of the runoff of blood through the fistula. Compensatory mechanisms include tachycardia and increased stroke volume so that cardiac output rises. Total blood volume is also increased. In large fistulas, left ventricular dilation, a widened pulse pressure, and high output heart failure occur. CT, MRI, or injection of contrast material into an artery proximal to the fistula confirms the diagnosis.
Generalized Pathologic Fistulas

Large intracranial arteriovenous fistulas most often occur in newborn infants in association with a vein of Galen malformation. The large intracranial left-to-right shunt results in heart failure secondary to the demand for high cardiac output. Patients with smaller communications may not have cardiovascular manifestations but may later be disposed to hydrocephalus (see Chapter 591.11) or seizure disorders. The diagnosis can often be made by auscultation of a continuous murmur over the cranium. Older children with more diffuse intracranial arteriovenous malformations may be recognized on the basis of intracranial calcification and high cardiac output without cardiac failure.

**Hepatic arteriovenous fistulas** may be generalized or localized in the liver and may be hemangioendotheliomas or cavernous hemangiomas. The fistula may be located between the hepatic artery and the ductus venosus or portal vein. Congenital hemorrhagic telangiectasia may also be present. Large arteriovenous fistulas are associated with increased cardiac output and heart failure. Hepatomegaly is usual, and systolic or continuous murmurs may be audible over the liver.

Peripheral arteriovenous fistulas generally involve the extremities and are associated with disfigurement, swelling of the extremity, and visible hemangiomas. Some are located in areas that result in upper airway obstruction. Because only a small minority results in large arterial runoff, cardiac failure is uncommon.

**TREATMENT**

Medical management of heart failure is initially helpful in neonates with these conditions; with time, the size of the shunt may diminish and symptoms spontaneously regress. Hemangiomas of the liver often eventually disappear completely. Large liver hemangiomas have been treated with steroids, ε-aminocaproic acid, interferon, local compression, embolization, or local irradiation; the beneficial effects of these management options are not firmly established because individual patients display marked variation in clinical course without treatment. Catheter embolization is becoming the treatment of choice for many patients with a symptomatic arteriovenous fistula. Embolic agents that have been used include detachable balloons, steel (Gianturco) coils, and liquid tissue adhesives (cyanoacrylate). Often, multiple procedures are necessary before flow is significantly reduced. Gamma knife radiosurgery has been used successfully in patients with cerebral arteriovenous malformations. Surgical removal of a large fistula may be attempted in patients with severe cardiac failure and lack of improvement with medical treatment. Surgical treatment may be contraindicated or unsuccessful when the lesion is extensive and diffuse or is located in a position where adjoining tissue may be injured during the surgery or related procedures.

**444.3 Generalized Arterial Calcification of Infancy/Idiopathic Infantile Arterial Calcification**

Robert M. Kliegman

Generalized arterial calcification of infancy (GACI) is a rare and often lethal autosomal recessive disorder characterized by calcification of muscular arteries with fibrotic myointimal proliferation and subsequent vascular stenosis leading to tissue ischemia, poor function or infarction. Diffuse arterial calcification may begin in utero leading to hydrops fetalis; in the neonate diffuse arterial calcification leads to respiratory distress and heart failure or myocardial infarction (coronary, pulmonary arteries), hypertension (renal arteries), and poor femoral pulses (aorta, femoral arteries).

Mutations in the ectonucleotide pyrophosphatase 1 gene (ENPP1) are noted in 75% of patients. Serum calcium, phosphate and alkaline phosphatase levels are normal and although the vascular calcification may be seen on plain x-rays (Fig. 444-3), ultrasonography (Fig. 444-4), or CT scans may reveal calcifications not visible on plain films.

A subset of patients with GACI have monoallelic or biallelic mutations in the adenosine triphosphatase–binding cassette subfamily C number 6 gene (ABCC6), which is the gene responsible for pseudoxanthoma elasticum (PXE). PXE, an autosomal recessive disorder, is classically associated with a later onset of ectopic mineralization of elastic fibers in the skin, eyes and arteries. In addition, some surviving infants with ENPP1 mutation develop PXE symptoms involving skin and retina (angioid streaking).

Infants with GACI have been treated with bisphosphonates with variable success. In addition, some survivors have developed hypophosphatemic rickets.
Arterial Calcifications Caused by Deficiency of CD73

This rare autosomal recessive disorder, due to mutations in the 5 exo-nucleotidase CD73 (NT5E) results in joint and arterial (lower extremity) calcification in adults. Patients present with intermittent claudication and joint pain. Onset is probably before adulthood, as patients may be undiagnosed with nonspecific findings during adolescence.

Bibliography is available at Expert Consult.
Bibliography

Primary (essential) hypertension occurs commonly in adults and, if untreated, is a major risk factor for myocardial infarction, stroke, and renal failure. In adults with hypertension, a 5 mm Hg increase in diastolic blood pressure (BP) increased the risk of coronary artery disease by 20% and the risk of stroke by 35%. Furthermore, hypertension is implicated in the etiology of nearly 50% of adults with end-stage renal disease. The prevalence of adult hypertension increases with age, ranging from 15% in young adults to 60% in individuals older than 65 yr.

Hypertensive children, although usually asymptomatic, already manifest evidence of target organ damage. Up to 40% of hypertensive children have left ventricular hypertrophy and hypertensive children have increased carotid intima–media thickness, a marker of early atherosclerosis. Primary hypertension during childhood often tracks into adulthood. Children with BP >90th percentile have a 2.4-fold greater risk of having hypertension as adults. Similarly, nearly half of hypertensive adults had a BP >90th percentile as children. There is also an association between childhood hypertension and early atherosclerosis in young adulthood.

PREVALENCE OF HYPERTENSION IN CHILDREN
In infants and young children, systemic hypertension is uncommon, with a prevalence of <1%, but when present, it is often indicative of an underlying disease process (secondary hypertension). Severe and symptomatic hypertension in children is usually caused by secondary hypertension. In contrast, the prevalence of primary essential hypertension, mostly in older school-age children and adolescents, has increased in prevalence in parallel with the obesity epidemic. School screening studies show that approximately 10% of U.S. youth overall have prehypertension and 2.5% have hypertension. The influence of obesity on elevated BP is evident in children as young as 2-5 yr old. Approximately 20% of American youth are obese, and up to 10% of obese youth have hypertension.

DEFINITION OF HYPERTENSION
The definition of hypertension in adults is BP ≥140/90 mm Hg, regardless of body size, sex, or age. This is a functional definition that relates level of BP elevation with the likelihood of subsequent cardiovascular events. Because hypertension-associated cardiovascular events, such as myocardial infarction or stroke, usually do not occur in childhood, the definition of hypertension in children is statistical rather than functional. The National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents published the Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents (Fourth Report) in 2004. This report established normal values based on the normative distribution of BP in healthy children and included tables with systolic and diastolic values for the 50th, 90th, 95th, and 99th percentile by age, sex, and height percentile. These normative tables can be obtained online at www.nhlbi.nih.gov/guidelines/hypertension/child_tbl.htm. The Fourth Report defined hypertension as average systolic blood pressure (SBP) and/or diastolic BP that is ≥95th percentile for age, sex, and height on ≥3 occasions. Prehypertension was defined as average SBP or diastolic BP that are ≥90th percentile but <95th percentile. In adolescents beginning at age 12 yr, prehypertension is defined as BP between 120/80 mm Hg and the 95th percentile. A child with BP levels

≥95th percentile in a medical setting but normal BP outside of the office has white coat hypertension.

The Fourth Report further recommended that if BP is ≥95th percentile, then the hypertension should be staged. Children with BP between the 95th and 99th percentile plus 5 mm Hg are categorized as stage 1 hypertension, and children with BP above the 99th percentile plus 5 mm Hg have stage 2 hypertension. Stage 1 hypertension, if asymptomatic and without target organ damage, allows time for evaluation before starting treatment, whereas stage 2 hypertension calls for more prompt evaluation and pharmacologic therapy (Fig. 445-1).

MEASUREMENT OF BP IN CHILDREN

The Fourth Report and the American Heart Association recommends that children 3 yr or older should have their BP checked during every healthcare episode (the AHA recommends annual BP checks). Selected children <3 yr old should also have their BP checked, including those with a history of prematurity, congenital heart disease, renal disease, solid-organ transplant, cancer, treatment with drugs known to raise BP, other illnesses associated with hypertension (neurofibromatosis, tuberous sclerosis, others), or evidence of increased intracranial pressure. The preferred method is by auscultation and a BP cuff appropriate for the size of the child's arm is used. Elevated readings should be confirmed on repeat visits before determining that a child is hypertensive. The BP should be measured with the child in the sitting position after a period of quiet for at least 5 min. Careful attention to cuff size is necessary to avoid over diagnosis, as a cuff that is too short or narrow artificially increases BP readings. A wide variety of bladder sizes should be available in any medical office where children are routinely seen. An appropriate sized cuff has an inflatable bladder that is at least 40% of the arm circumference at a point midway along the upper arm. The inflatable bladder should cover at least two thirds of the upper arm length and 80-100% of its circumference.

Systolic pressure is indicated by appearance of the 1st Korotkoff sound. Diastolic pressure has been defined by consensus as the 5th Korotkoff sound. Palpation is useful for rapid assessment of SBP, although the palpated pressure is generally about 10 mm Hg less than that obtained via auscultation. Oscillometric techniques are used frequently in infants and young children, but they are susceptible to artifacts and are best for measuring mean BP.

Ambulatory blood pressure monitoring (ABPM) is a procedure where the child wears a device that records BP frequently, usually every 20-30 min, throughout a 24 hr period while the child goes about usual daily activities, including sleep. This allows calculation of the mean daytime BP, sleep BP, and mean BP over 24 hr. The physician can also determine the proportion of BP measurements that are in the hypertensive range (BP load) and whether there is an appropriate decrease in BP during sleep (nocturnal dip). ABPM is particularly useful in the evaluation for white coat hypertension and may also be useful for determining risk of hypertensive target organ damage, evaluating resistance to pharmacologic therapy, and evaluating patients with hypertensive episodes on antihypertensive medication. ABPM is also useful for some special populations, such as children with chronic kidney disease, kidney transplant, and diabetes mellitus where it may provide important information on cardiovascular risk that cannot be determined as well by office measurements.

ETIOLOGY AND PATHOPHYSIOLOGY

BP is the product of cardiac output and peripheral vascular resistance. An increase in either cardiac output or peripheral resistance results in an increase in BP; if 1 of these factors increases while the other decreases, BP may not increase. When hypertension is the result of another disease process, it is referred to as secondary hypertension. When no identifiable cause can be found, it is referred to as primary (essential) hypertension. Many factors, including heredity, diet, stress, and obesity, may play a role in the development of primary hypertension. Secondary hypertension is most common in infants and younger children. The younger the child, the higher the BP and the presence of symptoms related to hypertension, the more likely there will be an underlying secondary cause of hypertension. Many childhood diseases can be responsible for chronic hypertension (Table 445-2) or acute/intermittent hypertension (Table 445-2). The most likely cause varies with age. Hypertension in the premature infant is sometimes associated with umbilical artery catheterization and renal artery thrombosis. Hypertension during early childhood may be caused by renal disease,
coarctation of the aorta, endocrine disorders, or medications. In older school-age children and adolescents, primary hypertension becomes increasingly common.

Secondary hypertension in children is most commonly caused by renal abnormalities; cardiovascular disease or endocrinopathies are additional etiologies. Renal (chronic glomerulonephritis, reflux or obstructive nephropathy, hemolytic uremic syndrome, polycystic or dysplastic renal diseases), or renovascular hypertension, account for approximately 90% of children with secondary hypertension. Renal parenchymal disease and renal artery stenosis lead to water and sodium retention thought to be, in part, secondary to increased renin secretion. Coarctation of the aorta should always be considered. Several endocrinopathies are associated with hypertension, usually those involving the thyroid, parathyroid, and adrenal glands. Systolic hypertension and tachycardia are common in hyperthyroidism; diastolic pressure is not usually elevated. Hypercalcemia, whether secondary to hyperparathyroidism or other causes, often results in mild elevation in BP because of an increase in vascular tone. Adrenocortical disorders (aldosterone-secreting tumors, sodium retaining congenital adrenal hyperplasia, Cushing syndrome) may produce hypertension in patients with increased mineralocorticoid secretion. It is important to consider conditions associated with real or apparent mineralocorticoid excess (Table 445-3) and thus a suppressed renin level form of secondary hypertension. Pheochromocytomas are catecholamine-secreting tumors that give rise to hypertension because of the cardiac and peripheral vascular effects of epinephrine and norepinephrine. Children with pheochromocytoma usually have sustained rather than intermittent or exercise-induced hypertension. Pheochromocytoma develops in approximately 5% of patients with neurofibromatosis. Rarely, secondary hypertension can be caused by pseudohypoparathyroidism, which leads to elevated BP in the face of a suppressed renin level. Such disorders include Liddle syndrome, apparent mineralocorticoid excess, and dexamethasone suppressible aldosteronism. Altered sympathetic tone can be responsible for acute or intermittent elevation of BP in children with Guillain-Barré syndrome, poliomyelitis, burns, and Stevens-Johnson syndrome. Sympathetic outflow from the central nervous system is also affected by intracranial lesions.

A number of drugs of abuse, therapeutic agents, and toxins may cause hypertension. Cocaine may provoke a rapid increase in BP and can

result in seizures or intracranial hemorrhage. Phencyclidine causes transient hypertension that may become persistent in chronic abusers. Tobacco use may also increase BP. Sympathomimetic agents used as nasal decongestants, appetite suppressants, and stimulants for attention deficit disorder produce peripheral vasoconstriction and varying degrees of cardiac stimulation. Individuals vary in their susceptibility to these effects. Oral contraceptives should be suspected as a cause of hypertension in adolescent girls, although the incidence is lower with the use of low-estrogen preparations. Immunosuppressant agents such as cyclosporine and tacrolimus cause hypertension in organ transplant recipients, and the effect is exacerbated by the co-administration of steroids. BP may be elevated in patients with poisoning by a heavy metal.

Children and adolescents with primary (essential) hypertension are commonly overweight, often have a strong family history of hypertension, and usually have BP values at or only slightly above the 95th percentile for age. Primary hypertension is the most common form of hypertension in adults, and it is recognized more often in adolescents than in young children. The cause of primary hypertension is likely to be multifactorial; obesity, genetic alterations in calcium and sodium transport, vascular smooth muscle reactivity, the renin–angiotensin system, sympathetic nervous system overactivity, and insulin resistance have been implicated in this disorder. Elevated uric acid levels may play a role in the pathophysiology of primary hypertension and proof-of-concept studies have confirmed that lowering of uric acid levels results in lower BP in overweight youth with hypertension or prehypertension. Some children and adolescents demonstrate salt-sensitive hypertension, a factor that is ameliorated with weight loss and sodium restriction.

Normotensive children of hypertensive parents may show abnormal physiologic responses that are similar to those of their parents. When subjected to stress or competitive tasks, the offspring of hypertensive adults, as a group, respond with greater increases in heart rate and BP than do children of normotensive parents. Similarly, some children of hypertensive parents may excrete higher levels of urinary catecholamine metabolites or may respond to sodium loading with greater weight gain and increases in BP than do those without a family history of hypertension. The abnormal responses in children with affected parents tend to be greater in the black population than among white individuals.

### CLINICAL MANIFESTATIONS

Children and adolescents with primary hypertension are usually asymptomatic; the BP elevation is usually mild and is detected during a routine examination or evaluation before athletic participation. These children may also be obese. Children with secondary hypertension can have BP elevations ranging from mild to severe. Unless the pressure has been sustained or is rising rapidly, hypertension does not usually produce symptoms. Therefore, clinical manifestations may instead reflect the underlying disease process, such as growth failure in children with chronic kidney disease. With substantial hypertension, headache, dizziness, epistaxis, anorexia, visual changes, and seizures may occur. Hypertensive encephalopathy (generalized or posterior reversible encephalopathy syndrome) is suggested by the presence of headache, vomiting, temperature elevation, visual disturbances, ataxia, depressed level of consciousness, CT abnormalities, and seizures (Fig. 445-2). Cardiac failure, pulmonary edema, and renal dysfunction (malignant hypertension) may occur in the face of marked hypertension. Bell palsy may be seen in asymptomatic or symptomatic patients.

### Hypertensive Crisis

Hypertensive crisis may manifest with decreased vision (retinal hemorrhages of hypertensive retinopathy) and papilledema, encephalopathy (headache, seizures, depressed level of consciousness), heart failure, or accelerated deterioration of renal function.

Subclinical hypertensive target-organ injury is a common clinical manifestation in children with essential hypertension. With the use of

echocardiography using pediatric normative data, left ventricular hypertrophy is detected in up to 40% of hypertensive children. Other markers of target organ damage that have been demonstrated in hypertensive children include increased carotid intima–media thickness, hypertensive retinopathy, and microalbuminuria. Children with pre-hypertension also have evidence of target organ damage, often at a magnitude intermediate between that of normotensive and hypertensive children.

DIAGNOSIS
The evaluation of the child with chronic hypertension should be directed toward uncovering potential underlying causes of the hypertension, evaluating for comorbidities, and screening for evidence of target organ damage. The extent of the evaluation for underlying causes of hypertension depends on the type of hypertension that is suspected. When secondary hypertension is a strong consideration, as in younger children with severe and symptomatic hypertension, an extensive evaluation may be necessary (Fig. 445-3). Alternatively, overweight adolescents with a family history of hypertension who have mild elevations of BP may need only a limited number of tests.

In all cases, a careful history and physical examination are warranted. A family history for early cardiovascular events should be obtained. Growth parameters should be determined to detect evidence of chronic disease. BP should be obtained in all 4 extremities to detect coarctation (thoracic or abdominal) of the aorta. Table 445-4 identifies other features of the physical examination that may provide evidence of an underlying cause of hypertension. Unless the history and physical examination suggest another cause, children with confirmed hypertension should have an evaluation to detect renal disease, including urinalysis, electrolytes, blood urea nitrogen, creatinine, complete blood count, urine culture, and renal ultrasound. Table 445-5 provides a more complete list of tests to consider in the clinical evaluation of a child with confirmed hypertension. Measuring serum potassium is essential because hypokalemia may be present in Liddle syndrome, glucocorticoid remedial aldosteronism, and apparent mineralocorticoid excess syndrome, while hyperkalemia may be seen in Gordon syndrome.

Renovascular hypertension is often associated with other diseases (Table 445-6) but may be isolated. Magnetic resonance or CT angiography can reveal renal artery stenosis, but fluoroscopic angiography may be needed, especially to detect intrarenal arterial stenosis (Fig. 445-4).

Primary hypertension often clusters with other risk factors. All hypertensive children should be screened for comorbidities that may increase cardiovascular risk, including hyperlipidemia and glucose intolerance. A fasting lipid panel and fasting glucose level should be obtained. In addition, a sleep history should be obtained in children with confirmed hypertension to screen for sleep disordered breathing, an entity that is associated with high BP, particularly in overweight children.

Left ventricular hypertrophy (LVH) is the most common manifestation of target-organ damage in hypertensive children. All children with confirmed hypertension should have echocardiography to evaluate for the presence of LVH. Left ventricular mass measurements should be indexed to height (m²) to account for the effect of body size. The presence of LVH is an indication to treat the hypertension with pharmacologic therapy.

PREVENTION
Prevention of high BP may be viewed as part of the prevention of cardiovascular disease and stroke, the leading cause of death in adults in the United States. Other risk factors for cardiovascular disease include obesity, elevated serum cholesterol levels, high dietary sodium intake, and a sedentary lifestyle, as well as alcohol and tobacco use. The

Figure 445-4 Renal angiogram in 7 yr old boy with hypertension. Right renal artery is visible with a string-of-beads appearance characteristic of fibromuscular dysplasia (arrows). The aorta and left renal artery appear normal. (From Tullus K, Brennan E, Hamilton G, et al: Renovascular hypertension in children, Lancet 371:1453–1463, 2008, p. 1454, Fig. 1.)
increase in arterial wall rigidity and blood viscosity that is associated with exposure to the components of tobacco may exacerbate hyperten-
sion. Population approaches to prevention of primary hypertension include a reduction in obesity, reduced sodium intake, and an increase in physical activity through school- and community-based programs.

**TREATMENT**

The Fourth Report recommended a management algorithm for children with confirmed hypertension according to whether the child has prehypertension, stage 1 hypertension, or stage 2 hypertension (see Figs. 445-1 and 445-5). The mainstay of therapy for children with asymptomatic mild hypertension without evidence of target-organ damage is therapeutic lifestyle modification with dietary changes and regular exercise. Weight loss is the primary therapy in obesity-related hypertension. It is recommended that all hypertensive children have a diet increased in fresh fruits, fresh vegetables, fiber, and nonfat dairy, and reduced in sodium. In addition, regular aerobic physical activity for at least 30-60 min on most days along with a reduction of sedentary activities to less than 2 hr per day is recommended. Indications for pharmacologic therapy include symptomatic hypertension, secondary hypertension, hypertensive target organ damage, diabetes (types 1 and 2), and persistent hypertension despite nonpharmacologic measures (Table 445-7). When indicated, antihypertensive medication should be initiated as a single agent at low dose (see Fig. 445-5). The dose can then be increased until the goal BP is achieved. Once the highest recommended dose is reached or if the child develops side effects, then a second drug from a different class can be added. Acceptable drug classes for use in children include angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, β-blockers, calcium channel blockers, and diuretics. Details on recommended doses of different

classes of antihypertensive medications for children can be found in the Fourth Report available free online at www.nhlbi.nih.gov/health/prof/heart/hbp/hbp_ped.pdf.

The goal of therapy for hypertension should be to reduce BP below the 95th percentile, except in the presence of chronic kidney disease, diabetes, or target-organ damage, when the goal should be to reduce BP to less than the 90th percentile. Angiotensin-converting enzyme inhibitors or angiotensin receptor blockers should be used for children with diabetes and microalbuminuria or proteinuric renal disease. β-Blockers or calcium channel blockers should be considered for hypertensive children with migraine headaches.

Severe, symptomatic hypertension is a hypertensive emergency that is often accompanied by cardiac failure, retinopathy, renal failure, encephalopathy, and seizures. Intravenous administration is often preferred so that the fall in BP can be carefully titrated (Table 445–8). Drug choices include labetalol, nicardipine, and sodium nitroprusside. Because too rapid a reduction in BP may interfere with adequate organ perfusion, a stepwise reduction in pressure should be planned. In general, the pressure should be reduced by 10% in the 1st hr, and 15% more in the next 3–12 hr, but not to normal during the acute phase of treatment. Hypertensive urgencies, usually accompanied by few serious symptoms such as severe headache or vomiting, can be treated either orally or intravenously. The Fourth Report also includes detailed information on antihypertensive drugs used for the management of severe hypertension in children.

Treatment of secondary hypertension must also focus on the underlying disease such as chronic renal disease, hyperthyroidism, adrenal–genital syndrome, pheochromocytoma, coartation of the aorta, or renovascular hypertension. The treatment of renovascular stenosis includes antihypertensive medications, angioplasty, or surgery (Fig. 445-6). If bilateral renovascular hypertension or renovascular disease in a solitary kidney is suspected, drugs acting on the renin-angiotensin axis are usually contraindicated because they may reduce glomerular filtration rates and produce renal failure.

Section 1
The Hematopoietic System

Chapter 446
Development of the Hematopoietic System
Robert D. Christensen and Robin K. Ohls

HEMATOPOIESIS IN THE HUMAN EMBRYO AND FETUS

Hematopoiesis is the process by which the cellular elements of blood are formed. In the developing human embryo and fetus, hematopoiesis is conceptually divided into 3 anatomic stages: mesoblastic, hepatic, and myeloid. Mesoblastic hematopoiesis occurs in extraembryonic structures, principally in the yolk sac, and begins between the 10th and 14th days of gestation. By 6–8 wk of gestation the liver replaces the yolk sac as the primary site of blood cell production, and during this time the placenta also contributes as a hematopoietic site. By 10–12 wk extraembryonic hematopoiesis has essentially ceased. Hepatic hematopoiesis occurs through the remainder of gestation, although hepatic production diminishes during the second trimester while bone marrow (myeloid) hematopoiesis increases. The liver remains the predominant erythropoietic organ (few if any neutrophils are produced in the human fetal liver) through 20–24 wk of gestation.

Each hematopoietic organ houses distinct populations of cells. At 18–20 wk the fetal liver is predominantly an erythropoietic organ, while the marrow produces both erythrocytes and neutrophils. The types of leukocytes present in the fetal liver and marrow differ with gestation. Macrophages precede neutrophils in the marrow, and the ratio of macrophages to neutrophils decreases as gestation progresses. Regardless of gestational age or anatomic location, production of all hematopoietic tissues begins with pluripotent stem cells capable of both self-renewal and clonal maturation into all blood cell lineages. Progenitor cells differentiate under the influence of hematopoietic growth factors (Table 446-1). Fetal hematopoietic growth factor production is independent of maternal growth factor production (Fig. 446-1).

Erythrocytes in the fetus are larger than in adults, and at 22–23 wk gestation the mean corpuscular volume can be as high as 135 fl (Fig. 446-2, upper panel). Similarly, the mean corpuscular hemoglobin is very high at 22–23 wk, and falls relatively linearly with advancing gestation (Fig. 446-2, lower panel). In contrast, the mean corpuscular hemoglobin concentration is constant throughout gestation at 34±1 g/dL. While the size and quantity of hemoglobin in erythrocytes diminish during gestation, the hematocrit and blood hemoglobin concentration gradually increase (Fig. 446-3, upper and lower panels, respectively).

Concentrations of platelets in the blood increase gradually between 22 and 40 wk gestation (Fig. 446-4) but the platelet size, assessed by mean platelet volume, remains constant at 8±1 fl. No differences are observed between males and females in fetal and neonatal reference ranges for erythrocyte indices, hematocrit, hemoglobin, platelet counts, or mean platelet volume measurements.

FETAL GRANULOCYTOPOIESIS

Neutrophils are first observed in the human fetus about 5 wk postconception as small clusters of cells around the aorta. The fetal bone marrow space begins to develop around the 8th wk postconception, and from 8–10 wk the marrow space enlarges, but no neutrophils appear there until 10.5 wk. From 14 wk through term, the most common granulocytic cell type in the fetal bone marrow space is the neutrophil. Neutrophils and macrophages originate from a common progenitor cell but macrophages appear prior to neutrophils in the fetus, first in the yolk sac, liver, lung, and brain, all before the bone marrow cavity is formed.

Granulocyte colony-stimulating factor (G-CSF) and macrophage colony-stimulating factor (M-CSF) are expressed in developing fetal bone as early as 6 wk postconception and both are expressed in the fetal liver as early as 8 wk. Granulocyte-macrophage colony-stimulating factor (GM-CSF) and stem cell factor also are distributed widely in human fetal tissues. However, no changes in expression of any of these factors, or of their specific receptors, appear to be the signal for fetal production of neutrophils or macrophages, as those signals have not yet been identified.

Fetal blood contains few neutrophils until the third trimester. At 20 wk gestation the blood neutrophil count is 0–500/mm³. Although mature neutrophils are scarce, progenitor cells with the capacity to generate neutrophil clones are abundant in fetal blood. When cultured in vitro in the presence of recombinant G-CSF, they mature into large colonies of neutrophils. The physiologic role of G-CSF includes upregulating neutrophil production, and this appears to be the case for the fetus and neonate, as well as for adults. Thus, the low quantities of circulating neutrophils the mid-trimester human fetus may be partly a result of low production of G-CSF. Monocytes isolated from the blood of adults produce G-CSF when stimulated with a variety of inflammatory mediators such as bacterial lipopolysaccharide (LPS) or interleukin (IL)-1. In contrast, monocytes isolated from the blood or organs of fetuses up to 24 wk gestation generate only small quantities of G-CSF protein and messenger RNA (mRNA) after lipopolysaccharide or IL-1 stimulation. Despite this, G-CSF receptors on the surface of neutrophils of newborn infants are equal in number and affinity to those on adult neutrophils.

In the fetus, actions of the granulocytopoietic factors (G-CSF, M-CSF, GM-CSF, and stem cell factor) are not limited to hematopoiesis. Receptors for each of these are located in areas of the fetal central nervous system and gastrointestinal tract, where their patterns of expression change with development. Important developmental roles exist for these factors beyond hematopoiesis.

FETAL THROMBOPOIESIS

Platelet production occurs from 2 pools of cells: megakaryocyte progenitors and megakaryocytes. Megakaryocyte progenitors are categorized as burst-forming unit–megakaryocytes (BFU-MK), which are primitive megakaryocyte progenitors, and colony-forming unit–megakaryocytes (CFU-MK), which are more differentiated. BFU-MK produce large multifocal colonies containing ≥50 megakaryocytes, whereas CFU-MK generate smaller (3–50 cells/colony) unifocal colonies. The colonies generated by BFU-MK of fetal origin contain significantly more megakaryocytes than do those of adult origin and on that basis are thought to represent somewhat more primitive cells. Megakaryocytes are identified by their morphologic characteristics, as they undergo endoreduplication, which results in large cells with
Thrombopoietin (TPO) is the physiologic regulator of platelet production and a primary, but not exclusive, regulator of platelet production and stimulates the proliferation and survival not only of megakaryocytic progenitors but also of erythroid, myeloid, and multipotent progenitors. Recombinant TPO supports the growth of megakaryocytic colonies of neonates and children and progenitors of preterm neonates are more sensitive to recombinant TPO than are progenitors of term neonates.

**FETAL ERYTHROPOIESIS**

Similar to hematopoietic production of other cell lines, fetal erythropoiesis is regulated by growth factors produced by the fetus, not by the mother. Erythropoietin (EPO) does not cross the human placenta. Stimulating maternal EPO production does not stimulate fetal erythropoiesis, and suppressing maternal erythropoiesis by hypertransfusion does not suppress fetal erythropoiesis.

It is unclear to what extent the mechanisms regulating erythropoiesis in adults are operative in the fetus. Of all the factors known to be involved in stimulating erythropoiesis, none plays a more central regulatory role than does EPO, a 30-39 kDa glycoprotein that binds to specific receptors on the surface of erythroid precursors and stimulates their differentiation and clonal maturation into mature erythrocytes.

EPO is produced in fetal liver during the first and second trimesters, principally by cells of monocyte/macrophage origin. After birth, the anatomic site of EPO production shifts to the kidney. The specific stimulus for this shift is unknown but may involve the increase in arterial oxygen tension that occurs at birth. Epigenetic modification of gene expression may also play a role, as it appears that renal and hepatic EPO genes are methylated to different degrees. Although EPO mRNA and protein can be found in the human fetal kidney, it is not known whether this production is biologically relevant. However, it appears that renal production of EPO is not essential for normal fetal erythropoiesis, as evidenced by the normal serum EPO concentrations and normal hematocrits of anephric fetuses.

**Hemoglobins in the Fetus and Neonate**

The evolutionary development of oxygen-carrying proteins, the hemoglobins, increased the ability of blood to transport oxygen. The
The time of appearance and quantitative relationships among the hemoglobins are determined by complex developmental processes.

**Embryonic Hemoglobins**

The blood of early human embryos contains 2 slowly migrating hemoglobins, Gower-1 and Gower-2, and Hb Portland, which has HbF-like mobility. The zeta (ζ) chains of Hb Portland and Gower-1 are structurally quite similar to α chains. Both Gower hemoglobins contain a unique type of polypeptide chain, the epsilon (ε) chain. Hb Gower-1 has the structure \( \alpha_2\epsilon_2 \), while Gower-2 has the structure \( \alpha_2\zeta_2 \). Hb Portland has the structure \( \zeta_2\gamma_2 \). In embryos of 4-8 wk gestation, the Gower hemoglobins predominate, but by the 3rd mo they have disappeared.

**Fetal Hemoglobin**

HbF contains γ polypeptide chains in place of the β chains of HbA. Its resistance to denaturation by strong alkali is the basis for determining the presence of fetal RBCs in the maternal circulation (the Kleihauer-Betke test). After the 8th wk, HbF is the predominant hemoglobin; at 24 wk gestation it constitutes 90% of the total hemoglobin. During the 3rd trimester, a gradual decline occurs, so that at birth HbF averages 70% of the total hemoglobin. Synthesis of HbF decreases rapidly postnatally (Fig. 446-7), and by 6-12 mo of age only a trace is present. Less than 2.0% can be detected by alkali denaturation in older children and adults.
During fetal life and early childhood, the rates of synthesis of \( \gamma \) and \( \beta \) chains and the amounts of HbA and HbF are inversely related. This relationship has been attributed to a “switch mechanism” similar to genetic regulatory mechanisms in bacteria, but the genetic, biologic, and developmental processes that direct a switchover from predominantly \( \gamma \)-chain synthesis in utero to predominantly \( \beta \)-chain synthesis after birth are unclear. It is not certain whether the mechanisms involve selective genetic inhibition or facilitation. The increase in the \( \alpha \) globin
Alterations of the Hemoglobins by Disease

Because hemoglobins containing $\gamma$ chains normally are present only very early in intrauterine life, in the past they were largely of theoretical interest. Interest has been renewed by the growing method of isolation of free fetal DNA in the maternal circulation, allowing for noninvasive fetal diagnosis of a variety of genetic traits, such as RhD (rhesus antigen D) positivity in the fetus of an RhD-negative mother. In addition, small amounts of the Gower hemoglobins have been detected in a few newborns with trisomy 13. Increased levels of Hb Portland have been found in cord blood of stillborn infants with homozygous $\alpha$-thalassemia.

HbF levels may be influenced by various factors. Because the HbF level is elevated during the 1st yr of life, knowledge of its normal decline is important (see Figs. 446-6 and 446-7). In persons heterozygous for $\beta$-thalassemia ($\beta$-thalassemia trait), postpartum decrease of HbF is delayed; approximately 50% of such persons have elevated levels of HbF ($>2\%$) in later life. In homozygous thalassemia (Cooley anemia) and in hereditary persistence of HbF, large amounts of HbF characteristically are found. In patients with major $\beta$-chain hemoglobinopathies (HbSS [homozygous hemoglobin S], HbSC [sickle cell hemoglobin C]), HbF usually is increased, particularly during childhood. Preterm infants treated with human recombinant EPO increase HbF production during active erythropoiesis. Moderate elevations of HbF may occur in many diseases accompanied by hematologic stress, such as hemolytic anemias, leukemia, and aplastic anemia, because of a minor population of RBCs that contain increased amounts of HbF. Tetramers of $\gamma$ chains ($\gamma_4$, or Hb Barts) or $\beta$ chains ($\beta_4$, HbH) may be found in $\alpha$-thalassemia syndromes.

The normal adult level of HbA2 (2.0-3.4%) is seldom altered. Levels of HbA2 $>3.4\%$ are found in most persons with the $\beta$-thalassemia trait and in those with megaloblastic anemias secondary to vitamin B12 and folic acid deficiency. Decreased HbA2 levels are found in those with iron-deficiency anemia (see Chapter 455) and $\alpha$-thalassemia (see Chapter 462).

**RED CELL LIFE SPAN OF THE FETUS AND NEONATE**

In general, the highest hematocrit during a person’s lifetime occurs at birth, and the lowest occurs about 10 wk later. The reasons for this rapid fall are complex, but a shortened life-span of fetal/neonatal RBC has been suggested as an important component. Specifically, the RBC life span during the fetal and neonatal period is generally thought to be considerably less than the 120 day erythrocyte life span found in normal adults. Estimates of an average 60-90 day life span were derived in the 1960s from studies of chromium ($^{51}$Cr)-labeled RBC. The “extinction time” is the number of days after transfusing labeled RBC when the label is completely gone from the circulating RBC, thus it estimates the maximal RBC life span. Recent studies indicate that the extinction time of fetal/neonatal RBC is similar to that of adults. For instance, fetal RBC transfused into an ABO-compatible mother, by a fetomaternal transfusion, have an extinction time of 120 days. Moreover, erythrocytes drawn from neonates, labeled with biotin, and transfused back to the neonate, have a half-disappearance time similar to adult donor erythrocytes.

It is possible that some fraction of fetal RBC survive 120 days and are then removed in the spleen by senescence, just as occurs case in healthy adults, while other RBC are removed prematurely by an active process. Neocytolysis is one possibility explaining the active process. Neocytolysis is the active removal of young erythrocytes that were generated in relatively hypoxic conditions, following normoxic or hyperoxic conditions. Neocytolysis is the process whereby the high hematocrit of persons acclimated to high altitude falls rapidly after descent to sea level (a process somewhat analogous to the change from fetal to postbirth oxygen saturations). It will be instructive to determine whether neocytolysis is, indeed, an important regulator of erythrocyte life span and bilirubin production after birth, and whether this process explains the marked fall in hematocrit but a normal RBC “extinction time” in human neonatal physiology.

Anemia is defined as a reduction of the hemoglobin concentration or red blood cell (RBC) volume below the range of values occurring in healthy persons. “Normal” hemoglobin and hematocrit (packed red cell volume) vary substantially with age and sex (Table 447-1). There are also racial differences, with significantly lower hemoglobin levels in African-American children than in white non-Hispanic children of comparable age (Table 447-2). Anemia is a significant global health problem affecting children and reproductive age women (Figs. 447-1 and 447-2).

Physiologic adjustments to anemia include increased cardiac output, augmented oxygen extraction (increased arteriovenous oxygen difference), and a shunting of blood flow toward vital organs and tissues. In

Sample size is 5,142 (white, 2,264; African-American, 2,878).

In addition, the concentration of 2,3-diphosphoglycerate increases within the RBC. The resultant “shift to the right” of the oxygen dissociation curve reduces the affinity of hemoglobin for oxygen and results in more complete transfer of oxygen to the tissues. The same shift in the oxygen dissociation curve can also occur at high altitude. Higher levels of erythropoietin (EPO) and consequent increased red cell production by the bone marrow further assist the body to adapt.

### HISTORY AND PHYSICAL EXAMINATION

As with any medical condition, a detailed history and thorough physical exam are essential when evaluating an anemic child. Important historical facts should include age, sex, race and ethnicity, diet, medications, chronic diseases, infections, travel, and exposures. A family history of anemia and/or associated difficulties such as splenomegaly, jaundice, or early age onset of gallstones is also of consequence. There often are few physical symptoms or signs that result solely from a low hemoglobin, particularly when the anemia develops slowly. Clinical findings generally do not become apparent until the hemoglobin level falls to <7-8 g/dL. Clinical features can include pallor, sleepiness,
irritability, and decreased exercise tolerance. Pallor can involve the tongue, nail beds, palms, or palmar creases. A flow murmur is often present. Ultimately, weakness, tachypnea, shortness of breath on exertion, tachycardia, cardiac dilation, and high-output heart failure will result from increasingly severe anemia, regardless of its cause. Unusual physical findings linked to particular underlying disease etiologies are discussed in detail in sections describing the associated disorders.

LABORATORY STUDIES

Initial laboratory testing should include hemoglobin, hematocrit, and red cell indices as well as a white blood cell count and differential, platelet count, reticulocyte count, and examination of the peripheral blood smear. The need for additional laboratory studies is dictated by the history, the physical, and the results of this initial testing.

DIFFERENTIAL DIAGNOSIS

Anemia is not a specific entity but rather can result from any of number of underlying pathologic processes. To narrow the diagnostic possibilities, anemias may be classified on the basis of their morphology and/or physiology (Fig. 447-3).

Anemias may be morphologically categorized on the basis of RBC size (mean corpuscular volume [MCV]), and microscopic appearance. They can be classified as microcytic, normocytic, or macrocytic based on whether the MCV is low, normal, or high, respectively. RBC size also changes with age, and normal developmental changes in MCV should be recognized before a designation is made (see Table 447-1). Examination of a peripheral blood smear often reveals changes in RBC appearance that will help to further narrow the diagnostic categories (Fig. 447-4).

Details regarding morphologic changes associated with particular disorders are described in subsequent sections.

Anemias may also be further divided on the basis of underlying physiology. The 2 major categories are decreased production and increased destruction or loss. The 2 groups are not always mutually exclusive. Decreased RBC production may be a consequence of ineffective erythropoiesis or a complete or relative failure of erythropoiesis. Increased destruction or loss may be secondary to hemolysis, sequestration, or bleeding. The peripheral blood reticulocyte percentage or absolute number will help to make a distinction between the 2 physiologic categories. The normal reticulocyte percentage of total RBCs during most of childhood is approximately 1%, with an absolute reticulocyte count of 25,000-75,000/mm³. In the presence of anemia, EPO production and the absolute number of reticulocytes should rise. Low or normal numbers of reticulocytes generally represent an inadequate response to anemia that is associated with relative bone marrow failure or ineffective erythropoiesis. Increased numbers of reticulocytes represent a normal bone marrow response to ongoing RBC destruction (hemolysis), sequestration, or loss (bleeding).

Figure 447-3 presents a useful approach to assessing the common causes of anemia in the pediatric age group. Children with microcytic anemia and low or normal reticulocyte counts most often have defects in erythroid maturation or ineffective erythropoiesis. Iron deficiency (see Chapter 455) is the most common cause. Thalassemia trait (see Chapter 462) constitutes the primary differential diagnosis when iron deficiency is suspected. Distinctions between these entities are presented in Table 455-1 (see Chapter 455). Chronic disease or inflammation (more often normocytic), lead poisoning, and sideroblastic anemias should also be considered and are discussed in other chapters. Microcytosis and elevated reticulocyte counts are associated with thalassemia syndromes and hemoglobins C and E (see Chapter 462). Notably, thalassemias and hemoglobinopathies are most commonly seen in patients of Mediterranean, Middle Eastern, African, or Asian descent.
Normocytic anemia and low reticulocyte count characterize a large number of anemias. The anemia of chronic disease/inflammation (see Chapter 455) is usually normocytic. The anemia associated with renal failure, primarily a result of reduced EPO production, will invariably be associated with clinical and laboratory evidence of significant kidney disease. Decreased or absent red cell production secondary to transient erythroid aplasia of childhood, infection, drugs, or endocrinopathy usually results in a normocytic anemia, as does bone marrow infiltration by malignancy. In the case of invading leukemia or malignancy, abnormal leukocytes or tumor cells in association with thrombocytopenia or reduced or elevated white cell counts may be seen. Acute bleeding, hypersplenism, and congenital dyserythropoietic anemia type II (see Chapter 452) are also normocytic.

In children with normocytic anemia and an appropriate (high) reticulocyte response, the anemia is usually a consequence of bleeding, hypersplenism, or ongoing hemolysis. In hemolytic conditions, reticulocytosis, indirect hyperbilirubinemia, and increased serum lactate dehydrogenase are indicators of accelerated erythrocyte destruction. There are many causes of hemolysis, resulting from conditions that are extrinsic (usually acquired) or intrinsic (usually congenital) to the red cell. Abnormal RBC morphology (e.g., spherocytes, sickle forms, microangiopathy) identified on the peripheral smear is often helpful in ascertaining the cause.

The anemia seen in children with macrocytic blood cells is sometimes megaloblastic (see Chapter 454), resulting from impaired DNA synthesis and nuclear development. The peripheral blood smear in megaloblastic anemias contains large macroovalocytes, and the neutrophils often show nuclear hypersegmentation. The major causes of megaloblastic anemia include folate deficiency, vitamin B12 deficiency, and rare inborn errors of metabolism. Other macrocytic anemias with low or normal reticulocyte counts include acquired and congenital (Diamond-Blackfan and Fanconi) aplastic anemias and hypothyroidism. Patients with trisomy 21 have macrocytic cells, although an accompanying anemia is generally not present. High MCV and reticulocytosis is seen in congenital dyserythropoietic anemias I and III, and in situations wherein hemolysis results in such a large outpouring of young red cells that the mean MCV is abnormally high.

Bibliography is available at Expert Consult.
Bibliography
Diamond-Blackfan anemia (DBA) is a rare, congenital bone marrow failure syndrome that usually becomes symptomatic in early infancy. More than 90% of cases are recognized in the 1st yr of life. The disorder is characterized by anemia, usually normochromic and macrocytic, reticulocytopenia, and insufficient or absent of red blood cell (RBC) precursors in an otherwise normally cellular bone marrow. Up to 50% of affected individuals have additional, extrahematopoietic anomalies.

**ETIOLOGY**

DBA associated mutations were initially identified in RPS19, a gene that encodes a component protein of the small 40S ribosomal subunit. Such RPS19 mutations, all dominantly inherited, were found to be present in approximately 25% of patients. Nine other DBA genes were subsequently recognized, each encoding a different small (40S) or large (60S) ribosomal subunit protein. Mutations in 1 of the 10 ribosomal
protein (RP) genes were ultimately identified in 50-70% of cases. Although the disorder is often referred to as a ribosomopathy, the mechanism by which RP haploinsufficiency leads to DBA has not been fully elucidated. One hypothesis is that unaffected RP s pile up and then bind and inhibit the p53 regulator, MDM2. This process allows p53 to accumulate, causing cell-cycle arrest and apoptosis of erythroid precursors.

Two distinct mutations in the hematopoietic transcription factor GATA-1 were identified in 2 siblings and 1 unrelated patient with corticosteroid-dependent DBA. It remains unclear whether two pathways, one related to ribosomal dysfunction and one to impaired GATA-1 production, independently cause the same phenotype, or, alternatively that DBA results from problems in a single pathway GATA-1 were identified in 2 siblings and 1 unrelated patient with precursors.

**Epidemiology**

DBA affects about 7 individuals per 1 million live births. It is primarily an autosomal dominant disease, although other inheritance patterns may yet be demonstrated. Notably, there is substantial phenotypic diversity in DBA, even in families whose members share the same mutation, suggesting that additional genetic modifiers affect phenotypic expression of the disease. International consensus recommendations suggest that a diagnosis of “nonclassical” DBA be applied to family members harboring an established mutation or those without a known mutation but with an associated anomaly or laboratory abnormality.

**Clinical Manifestations**

Profound anemia usually becomes evident by 2-6 mo of age, occasionally somewhat later. Approximately 25% of patients are anemic at birth and hydrops fetalis occurs rarely; 92% are diagnosed within the first year of life. Approximately 50% of patients have congenital anomalies and more than 1 anomaly is found in 21% of individuals with DBA (Table 448-1). Craniofacial abnormalities are the most common (50% of patients) and include hypertelorism, snub nose, and high arched palate. Skeletal anomalies, mostly upper limb and hand, affect 30% of patients. Thumb abnormalities, including flattening of the thenar eminence and triphalangeal thumb, may be bilateral or unilateral. The radial pulse may be absent. Genitourinary (38% of patients), cardiac (30% of patients), ophthalmologic, and musculoskeletal anomalies have also been identified. Short stature is common, but it is often unclear whether this characteristic results from the disease itself, related therapies, or both.

**Laboratory Findings**

The RBCs are usually macrocytic for age, but no hypersegmented neutrophils or other characteristics of megaloblastic anemia are appreciated on the peripheral blood smear. Red cell enzyme patterns are similar to those of a "fetal" RBC population with increased expression of "i" antigen and elevated fetal hemoglobin. Erythrocyte adenosine deaminase (ADA) activity is increased in most patients with this disorder, a finding that helps distinguish congenital RBC aplasia from acquired transient erythroblastic anemia of childhood (see Chapter 450). Because elevated ADA activity is not a fetal RBC feature, measurement of this enzyme may be particularly helpful when diagnosing DBA in very young infants. Thrombocytosis or, rarely, thrombocytopenia, and occasionally neutropenia, may also be present. Reticulocyte percentages are characteristically very low despite severe anemia. Bone marrow erythrocyte precursors are markedly reduced in most patients; other marrow elements are usually normal. Serum iron levels are elevated. Unlike Fanconi anemia, there is no increase in chromosomal breaks when lymphocytes are exposed to alkylating agents.

**Differential Diagnosis**

DBA must be differentiated from other anemias associated with low reticulocyte counts. The syndrome of transient erythroblastic anemia of childhood (TEC) is often the primary alternative diagnosis. Table 450-1 in Chapter 450 shows a useful comparison of findings in these two disorders. TEC often is differentiated from DBA by its relatively late onset, although it occasionally develops in infants <6 mo of age (see Chapter 450). Macrocytosis, congenital anomalies, fetal red cell characteristics, and elevated erythrocyte ADA are generally associated with DBA and not with TEC.

Other inherited macrocytic bone marrow failure syndromes, particularly Fanconi anemia and Shwachman-Diamond syndrome, should also be considered in the differential as should meydysplastic syndrome. Hemolytic disease of the newborn can also mimic features of DBA because it can have a protracted course and can be coupled with markedly reduced erythropoiesis. The anemia in this disorder usually resolves spontaneously at 5-8 wk of age. Several types of chronic hemolytic disease may be complicated by aplastic crisis, characterized by reticulocytopenia and decreased numbers of RBC precursors. This event usually occurs after the first several mo of life and is often caused by parvovirus B19 infection (see Chapter 450). Infection with parvovirus B19 (see Chapter 251) in utero also may be associated with pure RBC aplasia in infancy, and even with hydrops fetalis at birth. When diagnosing DBA in young infants, it is important to rule out parvovirus B19 infection using the polymerase chain reaction. Other infections, including HIV, as well as drugs, immune processes, and Pearson syndrome (see Chapter 449) should also be ruled out.

| Table 448-1 Range of Congenital Anomalies Observed in Diamond-Blackfan Anemia |
|---------------------------------|---------------------------------|-----------------------------------|
| Craniofacial | Hypertelorism | Broad, flat nasal bridge |
| | Cleft palate | High arched palate |
| | Microcephaly | Microny 
| | | Microtia |
| | Low-set ears | Low hairline |
| | Epicanthus | Ptosis |
| Ophthalmologic | Congenital glaucoma | Strabismus |
| | | Congenital cataract |
| Neck | Short neck | Webbed neck |
| | | Sprengel deformity |
| | | Klippel-Feil deformity |
| Thumbs | Triphalangeal | Duplex or bifid |
| | | Hypoplastic |
| | | Flat thenar eminence |
| | | Absent radial artery |
| Urogenital | Absent kidney | Horseshoe kidney |
| | | Hypospadias |
| Cardiac | Ventricular septal defect | Atrial septal defect |
| | Coarctation of the aorta | Complex cardiac anomalies |
| Other musculoskeletal | Growth retardation | Syndactyly |
| Neuromotor | Learning difficulties | 

The list includes the anomalies that are most characteristic of DBA but is not exhaustive. Multiple anomalies, most commonly including craniofacial, are present in up to 25% of affected individuals.

TREATMENT

Corticosteroids are a mainstay of therapy, and approximately 80% of patients initially respond. Because corticosteroids impair linear growth as well as physical and neurocognitive development, many hematologists maintain infants on chronic transfusion therapy and delay the start of steroids until after age 1 yr. Prednisone or prednisolone in doses totaling 2 mg/kg/day is used as an initial trial. An increase in RBC precursors is usually seen in the bone marrow 1-3 wk after therapy is begun and is followed by peripheral reticulocytosis. The hemoglobin can reach normal levels in 4-6 wk, although the rate of response is quite variable. Once it is established that the hemoglobin concentration is increasing, the dose of corticosteroid may be reduced gradually by tapering and then by eliminating all except a single, lowest effective daily dose. This dose may then be doubled, used on alternate days, and tapered still further while maintaining the hemoglobin level at ≥9 g/dL. The target maintenance dose should not exceed 0.5 mg/kg/day or 1 mg/kg every other day. In some patients, very small amounts of prednisone, as low as 2.5 mg twice a wk, may be sufficient to sustain adequate erythropoiesis. Scheduled surveillance examinations and testing for corticosteroid side effects should be pursued in all patients, regardless of dose. Appropriate Pneumocystis prophylaxis should be used after the first month of high-dose steroids and continued until the patient is on low-dose alternate-day therapy. Many children with DBA stop taking corticosteroids, usually because of unacceptable side effects or the evolution of corticosteroid refractoriness. Only 37% of patients in the Diamond-Blackfan Anemia Registry (DBAR) (http://www.dbar.org/) remained on corticosteroids.

Patients who are nonresponders or who fail to tolerate corticosteroid therapy require transfusions at intervals of 3-5 wk to maintain a hemoglobin level greater than 8 g/dL. Some younger children may require hemoglobin levels greater than 9 g/dL in order to sustain normal growth and activities. Appropriate screening and, ultimately, the initiation of chelation therapy will be required as excess iron accumulates secondary to repeated transfusions. In one case report, a patient with DBA who was treated with l-leucine became transfusion independent and remained in remission at >5 mo.

Spontaneous remission of anemia with independence from steroid or red cell transfusion therapy has been reported. The likelihood of remission is 25% by age 25 yr, with the majority of patients experiencing remission during the first decade. Mild macrocytic anemia and increased erythrocyte ADA levels persist in these circumstances.

Hematopoietic stem cell transplantation (HSCT) can be curative. As the best outcomes occur using human leukocyte antigen (HLA)-matched sibling donors in patients 9 yr of age or younger. HLA-matched sibling HSCT is recommended in affected, transfusion dependent children between the ages of 3 and 9 yr. It is important that sibling donors be carefully screened, including genotype if known, to ensure that the donor does not carry the patient’s DBA gene. Improvements in alternative donor HSCT suggests that this modality may also provide an important option for select patients.

PROGNOSIS

DBA has been identified as a cancer predisposition syndrome. The risk is increased for myelodysplastic syndrome, acute myeloid leukemia, colon carcinoma, osteogenic sarcoma, and female genital cancers. The overall actuarial survival of all patients with DBA is approximately 75% at age 40 yr, with approximately 87% for those maintained on steroids, and approximately 57% for transfusion-dependent patients. Of reported deaths, 67% were treatment related and 22% were DBA-related (malignancy and severe aplastic anemia).

Bibliography
Pearson marrow-pancreas syndrome is a rare mitochondrial disorder that presents with a hypoplastic anemia that may be initially confused with Diamond-Blackfan syndrome or transient erythroblastopenia of childhood. The marrow failure usually appears in the neonatal period and is characterized by a macrocytic anemia and, occasionally, neutropenia and thrombocytopenia. There are vacuolated erythroblasts and myeloblasts in the bone marrow. This disorder is considered a unique variant of congenital sideroblastic anemia as the marrow also contains ringed sideroblasts. The hemoglobin F level is elevated. There is multiorgan involvement manifested by failure to thrive and symptoms of exocrine pancreas dysfunction, liver and renal tubular defects, malabsorption, and myopathy. Endocrine dysfunction has also been reported. In rare cases, when the disease is not fatal in early childhood, the disorder may evolve to include symptoms consistent with Kearns-Sayre syndrome.

This disorder is caused by a mitochondrial DNA deletion of variable size and location that is similar to the mitochondrial DNA (mtDNA) deletion found in Kearns-Sayre syndrome. There is heterogeneity in different tissues and between patients, accounting for the variable clinical picture. The proportion of deleted mtDNA in the bone marrow correlates with the severity of the hematologic picture, and a change in the percentage of tissue mtDNA types over time may be associated with spontaneous improvement of red blood cell hypoproliferation. Therapy for the hematologic manifestations of the disease is primarily supportive and includes red cell transfusions to correct anemia and granulocyte colony-stimulating factor to reverse episodes of severe neutropenia.

Bibliography

Transient erythroblastopenia of childhood (TEC) is the most common acquired red cell aplasia occurring in children. It is more prevalent than congenital hypoplastic (Diamond-Blackfan) anemia. This syndrome of severe, transient hypoplastic anemia occurs mainly in previously healthy children between 6 mo and 3 yr of age; most of the children are older than 12 mo at onset. Only 10% of affected patients are >3 yr of age. The annual incidence is estimated to be 4.3 cases per 100,000 children, although it is likely higher, because many cases might go undiagnosed and resolve spontaneously. The suppression of erythropoiesis has been linked to immunoglobulin (Ig) G, IgM, and cell-mediated mechanisms. Familial cases have been reported, suggesting
a hereditary component. TEC often follows a viral illness, although no specific virus has been consistently implicated.

The temporary suppression of erythropoiesis results in reticulocytopenia and moderate to severe normocytic anemia. Some degree of neutropenia occurs in up to 20% of cases. Platelet numbers are normal or elevated. Similar to the situation observed in iron-deficiency anemia and other red blood cell (RBC) hypoplasias, thrombocytosis is presumably caused by increased erythropoietin, which has some homology with thrombopoietin. Mean corpuscular volume (MCV) is characteristically normal for age, and fetal hemoglobin (HbF) levels are normal before the recovery phase. RBC adenosine deaminase levels are normal in this disorder, thus contrasting with the elevation noted in most cases of congenital hypoplastic anemia (Table 450-1). Differentiation from the latter disease is sometimes difficult, but differences in age at onset and in age-related MCV, HbF, and adenosine deaminase are usually helpful. The peak occurrence of TEC coincides with that of iron-deficiency anemia in infants receiving milk as their main caloric source; differences in MCV should help to distinguish between these 2 disorders.

Virtually all children recover within 1-2 mo. RBC transfusions may be necessary for severe anemia in the absence of signs of early recovery. The anemia develops slowly, and significant symptoms usually develop only with severe anemia. Corticosteroid therapy is of no value in this disorder. Any child with presumed TEC who requires >1 transfusion should be reevaluated for another possible diagnosis. In rare instances, a prolonged case of apparent TEC may be caused by parvovirus-induced RBC aplasia, occurring in children with hemolytic anemia or congenital or acquired immunodeficiencies.

**RED CELL APLASIA ASSOCIATED WITH PARVOVIRUS B19 INFECTION**

Parvovirus B19 is a common infectious agent that causes erythema infectiosum (fifth disease) (see Chapter 251). It is also the best-documented viral cause of RBC aplasia in patients with chronic hemolysis, patients who are immunocompromised, and fetuses in utero. This small, nonenveloped single-stranded virus is particularly infective and cytotoxic to marrow erythroid progenitor cells, interacting specifically via binding to the red cell P antigen. In addition to decreased or absent erythroid precursors, characteristic nuclear inclusions in erythroblasts and giant pronormoblasts may be seen under the light microscope in bone marrow specimens. The virus does not cause significant anemia in immunocompetent individuals with normal red cell life spans.

**CHRONIC HEMOLYSIS**

Because parvovirus infection is usually transient, with recovery occurring in <2 wk, anemia is either not present or not appreciated in otherwise normal children whose peripheral RBC life span is 100-120 days. The RBC life span is much shorter in patients with hemolysis secondary to conditions such as hereditary spherocytosis, immune hemolytic anemia, or sickle cell disease. In these children, a brief cessation of erythropoiesis can cause severe anemia, a condition known as an aplastic crisis. When a definitive diagnosis is required, the work-up should include serum parvovirus IgM and IgG titers and, if needed, viral detection using polymerase chain reaction (PCR) techniques. Recovery from moderate to severe anemia is usually spontaneous, heralded by a wave of nucleated RBCs and subsequent reticulocytosis in the peripheral blood. A RBC transfusion may be necessary if the anemia is associated with significant symptoms. Notably, parvovirus-induced aplastic crisis usually occurs only once in children with chronic hemolysis. In families with >1 child affected with a hemolytic disorder, parents should be warned that a similar aplastic episode can occur in the other children if they have not been previously infected.

**IMMUNODEFICIENCY**

Persistent parvovirus infection may occur in children with congenital immunodeficiency diseases, lymphoproliferative disorders, those being treated with immunosuppressive agents, and those with HIV/AIDS, because these children may be unable to mount an adequate antibody response. The resultant pure RBC aplasia may be severe, and affected children may be thought to have TEC. This type of RBC aplasia differs from TEC in that there is no spontaneous recovery and >1 transfusion is often needed. The diagnosis of parvovirus infection is made by PCR of peripheral blood or bone marrow DNA because the usual serologic responses, reflected by parvovirus serum IgM or IgG titers, are impaired in immunodeficient children. In chronically infected patients, the disease may be treated with high doses of intravenous immunoglobulin, which contains neutralizing antibody to parvovirus and is effective in the short term.

**MISCARRIAGE AND HYDROPS FETALIS**

Parvovirus infection and destruction of erythroid precursors can also occur in utero. Such events are associated with increased fetal wastage in the first and second trimesters. Infants may be born with hydrops fetalis (see Chapter 103) and anemia. The presence of persistent congenital parvovirus infection is detected by PCR of peripheral blood and/or bone marrow DNA, because immunologic tolerance to the virus can prevent the usual development of specific antibodies.

**OTHER RED CELL APLASIAS IN CHILDREN**

Acquired red cell aplasia in adults is usually mediated by a chronic antibody and often associated with disorders such as chronic lymphocytic leukemia, lymphoma, thymoma, lymphoproliferative disorders, and systemic lupus erythematosus. This chronic antibody-mediated type of RBC aplasia, often responsive to immunosuppressive therapy,

is quite rare in childhood. Cases of acquired pure red cell aplasia, attributable to T-cell suppression, have also been described.

Certain drugs, such as chloramphenicol, also can inhibit erythropoiesis in a dose-dependent manner. Reticulocytopenia, erythroid hypoplasia, and vacuolated pronormoblasts in the bone marrow are reversible effects of this drug. These effects are distinct from the idiosyncratic and rare development of severe aplastic anemia in chloramphenicol recipients. Acquired antibody-mediated pure red cell aplasia has also been found to be a rare complication in chronic kidney disease patients treated with erythropoiesis-stimulating agents. In addition to discontinuing erythropoiesis-stimulating agents therapy and addressing anemia with red cell transfusions, further treatment may include immunosuppression and renal transplantation.

Bibliography
The anemia of chronic disease (ACD), also referred to as anemia of inflammation, is found in conditions where there is ongoing immune activation. It occurs in a wide range of disorders including infections, malignancies, autoimmunity, and graft-versus-host disease. A similar anemia is associated with chronic kidney disease. ACD is typically a mild to moderate normocytic, normochromic, hypoproliferative anemia associated with a decreased serum iron and low transferrin saturation.

ETIOLOGY
Decreased red cell life span, impaired erythropoiesis, and an increased uptake of iron in the reticuloendothelial system are important mechanisms contributing to the anemia. The modest reduction in erythocyte longevity is perhaps the least well understood part of the pathophysiology of ACD. Elevated levels of cytokines such as interleukin-1 may increase the macrophage’s ability to ingest and destroy erythrocytes. Defective erythropoiesis, both proliferation and differentiation of precursors, has been attributed to immune cell/cytokine-driven inhibition of erythropoietin production and suppression of the bone marrow.

ACD associated alterations in iron recycling is characterized by an accumulation of iron in reticuloendothelial macrophages despite low levels of serum iron. The diversion of iron from the circulation into the reticuloendothelial system results in functional iron deficiency, which results in the impaired heme synthesis and iron-restricted erythropoiesis that contribute to anemia. These alterations in iron metabolism have been attributed to inflammation-associated excess synthesis of hepcidin, a key regulatory protein that controls intestinal iron absorption and tissue distribution. Hepcidin, although mainly synthesized by hepatocytes, is also expressed in other cells, including monocytes and macrophages. It functions by binding to and initiating the degradation of the iron exporter, ferroportin.

CLINICAL MANIFESTATIONS
Although the important symptoms and signs associated with ACD are those of the underlying disease, the mild to moderate anemia can affect the patient's quality of life.

LABORATORY FINDINGS
Hemoglobin concentrations are generally 6-9 g/dL. The anemia is usually normochromic and normocytic, although some patients have modest hypochromia and microcytosis, particularly if there is concomitant iron deficiency. Absolute reticulocyte counts are normal or low, and leukocytosis is common. The serum iron level is low, without the increase in serum transferrin that occurs in iron deficiency. This pattern of low serum iron and low-to-normal iron-binding protein (serum transferrin) is a regular and valuable diagnostic feature. The serum ferritin level may be elevated. The bone marrow has normal cellularity; the red blood cell precursors are decreased or adequate, marrow hemosiderin may be increased, and granulocytic hyperplasia may be present.

TREATMENT
The best approach to ACD is the treatment, when possible, of the underlying disorder. If the associated systemic disease can be controlled, the anemia will improve or resolve. Transfusions raise the hemoglobin concentration temporarily but are rarely indicated. Erythropoietic stimulating agents (ESAs), such as recombinant human erythropoietin (EPO) or related extended half-life formulations, increase the hemoglobin level and improve activity and the sense of well-being. When using ESAs, treatment with iron is usually necessary to produce optimal effect. Response to these agents is highly variable and poorly responsive patients may require high doses to reach target hemoglobin levels. In adults, such high doses are associated with a higher incidence of adverse events, such as stroke, cardiovascular events, cancer progression, and death, leading the FDA to require a black box warning on labels.

ACD does not respond to iron alone unless there is concomitant deficiency. Unfortunately it is a common clinical challenge to identify iron deficiency in patients with an inflammatory disease (see Chapters 447 and 455). In this circumstance, a trial of iron therapy might be helpful, although there may be no response as persistent inflammation impairs iron absorption and utilization; intravenous iron may further increase hepcidin production. Therapeutic agents that target the hepcidin–ferroportin axis are under investigation.

Bibliography is available at Expert Consult.

451.2 Anemia of Renal Disease
Norma B. Lerner

Anemia is common in children with chronic kidney disease (CKD). The anemia is usually normochromic, and the absolute reticulocyte count is normal or low. While most patients with end-stage renal disease (ESRD) are anemic, earlier stages of CKD are associated with a lower prevalence. In adults, lower glomerular filtration rate (GFR) has been correlated with lower hemoglobin concentration, and hemoglobin has been reported to decline below a GFR threshold of 40-60 mL/min/1.73 m². In children with CKD, hemoglobin levels decline as the GFR decreases below 43 mL/min/1.73 m².

Decreased hemoglobin values are linked to increased incidence of left ventricular hypertrophy, impaired physical activity, and a reduced quality of life in pediatric patients with CKD. In those with ESRD who are on dialysis, anemia is also associated with increased risk of hospitalization and mortality.

ETIOLOGY
Although the anemia of CKD shares many features with the ACD, its predominant cause is decreased EPO production by diseased kidneys. Other important causes include absolute and/or functional iron deficiency as a result of chronic blood loss (from blood sampling, surgeries, and dialysis) and disturbances in the iron metabolic pathway. Higher hepcidin levels have also been implicated in the anemia of CKD. Hepcidin is filtered by the glomerulus and excreted by the kidney; serum concentrations are increased in patients with decreased
Bibliography

GFR. Inflammation may also be a contributing factor in pediatric dialysis patients who have elevated levels of proinflammatory cytokines. Hyperparathyroidism and deficiencies of vitamin B₁₂, folate, and carnitine may also have a role in anemia of CKD.

LABORATORY FINDINGS
Anemia in children with CKD is defined by age: hemoglobin (Hb) <11.0 g/dL (0.5-5 yr), <11.5 g/dL (5-12 yr), <12 g/dL (12-15 yr), <13.0 g/dL (males older than 15 yr), and <12.0 g/dL (females older than 15 yr). The anemia of CKD is hypoproliferative and usually normocytic and normochromic, unless there is concomitant iron deficiency or vitamin deficiency. The EPO level and absolute reticulocyte count are usually low. White cell and platelet counts are generally normal. Ferritin will be low if there is accompanying iron deficiency, and high if there is associated inflammation.

TREATMENT
Oral iron therapy is recommended for all pediatric CKD patients with anemia. Consideration of IV iron therapy may be given for those receiving maintenance hemodialysis. Oral iron at 3-6 mg of elemental iron/kg of target dry weight once daily for 3 mo and possibly IV iron if transferrin saturation (serum iron × 100/total iron-binding capacity) and/or ferritin fail to improve is recommended.

ESAs are the mainstay of therapy and, particularly for children with ESRD, these medications have greatly reduced the need for frequent transfusions, decreasing the incidence of associated iron overload and alloimmunization. It is suggested to start ESA in all children with CKD when Hb concentrations are at 9-10 g/dL, with a goal of 11-12 g/dL (some recommend 11-13 g/dL) for children on maintenance ESA therapy. Dosing varies with age and dialysis modality. Darbepoetin, a synthetic form of EPO, appears to be equally effective as recombinant human EPO and has the benefit of less-frequent dosing as a consequence of a longer half-life. Iron therapy should be continued when using ESAs as treatment demands additional iron for hemoglobin synthesis.

A subset of patients is hyporesponsive to ESAs. In the past, pediatric nephrologists often responded to EPO resistance by further escalating the dose. The increased incidence of adverse events associated with dose escalation in the adult nondialysis CKD patients has prompted some concern about this approach. Several pediatric studies have demonstrated the value of IV iron supplementation in the setting of ESA hyporesponsiveness. In the rare case in which antibody-mediated (to EPO) pure red cell aplasia develops, ESA therapy should be stopped. A study including pediatric hemodialysis patients showed a nearly 50% decrease in hepcidin levels during treatment, suggesting that for those with ESA hyporesponsiveness and iron-restricted erythropoiesis, more frequent or longer duration sessions might be of benefit.

Bibliography is available at Expert Consult.
Bibliography
The congenital dyserythropoietic anemias (CDAs) are a heterogeneous class of inherited disorders resulting from abnormalities of late erythropoiesis. These rare conditions are characterized by variable degrees of anemia, ineffective erythropoiesis, and secondary hemochromatosis. Dyserythropoiesis is the major cause of anemia but a shortened half-life of circulating red cells may also contribute. The CDAs have historically been classified into 3 major types (I, II, and III) based upon distinctive bone marrow morphology and clinical features, although additional subgroups and variants have also been identified.

**TYPE I CONGENITAL DYSERYTHROPOIETIC ANEMIA**

**Pathogenesis**

Type I CDA is an autosomal recessive disorder. The causative gene (CDAN1) was mapped to chromosome 15 between q15.1 and q15.3 and then successfully cloned. The gene encodes codanin-1, which is a ubiquitously expressed protein that may expedite histone assembly into chromatin and regulate the cell cycle. Although the majority of patients with bone marrow characteristics indicative of CDA1 have mutations within CDAN1, such mutations have not been detected in approximately 20% of families. Two distinctive mutations in the gene C15ORF4, predicted to encode an endonuclease, have been identified in different CDA I pedigrees.

**Clinical Manifestations**

As of 2011, there were 169 cases from 143 families recorded in the literature. Most families were from Europe and the Middle East. Although CDA I may be diagnosed at any age, most cases are recognized during childhood or adolescence. CDA I is rarely diagnosed in utero. In addition to anemia-related symptoms, other findings often include splenomegaly, jaundice, and hepatomegaly. In more severe cases, evidence of extramedullary hemopoiesis in frontal or parietal bones of the skull and in paravertebral tumors may be present. Cholelithiasis and iron overload develop over time. Type I CDA has been associated with dysmorphic features in 4-14% of cases, primarily involving the digits (syndactyly, absence of nails, supernumerary toes). Retinal angiod streaks and macular abnormalities also have been reported.

**Laboratory Findings**

Hemoglobin concentrations generally range between 7 and 11 g/dL. The anemia is usually macrocytic (mean corpuscular volume 100-120 fL), but normocytic indices may be seen during childhood. Anisopoikilocytosis is appreciated on the peripheral blood smear. In some cases, normoblasts and basophilic stippling of red blood cells (RBCs) may be seen. The reticulocyte count is inadequate for the degree of anemia. Laboratory evidence of iron overload may be present. The bone marrow aspirate shows erythroid hyperplasia, megaloblastosis, and basophilic stippling. Binucleated and, more rarely, multinucleated polychromatophilic erythroblasts are also appreciated. Incompletely divided cells with thin chromatin bridges between nuclei of pairs of erythrocytes are highly specific for type I CDA. Electron microscopy is the gold standard for diagnosis, revealing erythroblasts with a characteristic “Swiss cheese” heterochromatin pattern.

**Treatment**

Treatment of this disorder is primarily supportive. Approximately 50% of neonates with CDA I will need at least 1 red cell transfusion and some may remain transfusion dependent over subsequent years. Adolescents and adults may only require episodic transfusions during aplastic crises, infection or pregnancy. If anemia is further exacerbated by co-inherited disorders, such as thalassemia or RBC enzymopathy, the patient may become transfusion dependent. The most important long-term complication is hemosiderosis, which is caused by increased intestinal absorption of iron and ineffective erythropoiesis; consequently, transfusions should be avoided when possible to prevent further iron loading. Regular phlebotomies result in normal ferritin concentrations but if this approach is untenable oral chelation therapy should be employed when repeated ferritin levels exceed 1000 µg/L. In many cases of documented CDA type I, interferon-α has effectively raised the hemoglobin concentration, reduced splenomegaly, and reduced iron overload. Patients do not respond to erythropoietin. Splenectomy is generally not
recommended. Cholecystectomy is often required. Allogeneic bone marrow transplantation from a human-leukocyte-antigen-identical sibling has been successful in a few severe cases.

**TYPE II CONGENITAL DYSERYTHROPOIETIC ANEMIA**

**Pathogenesis**

CDA II is also an autosomal recessive disorder. Genome-wide linkage analysis identified a region of chromosome 20p11.2 as the location of the candidate CDAN2 gene that was later identified to be the SEC23B gene. This gene is known to encode the cytoplasmic coat protein (COP) II component SEC23B that is involved in endoplasmic reticulum vesicle trafficking. SEC23B gene mutations have been associated with the majority of CDA II cases.

**Clinical Manifestations**

As of 2011, there were 454 cases from 356 families with CDA II recorded, making it the most common form of CDA. Families were mostly from Europe and the Middle East. In contrast to CDA I, this diagnosis is usually made later in life, often because symptoms may be milder. Also, CDA II may be initially misdiagnosed as hereditary spherocytosis. Characteristic findings can include anemia, jaundice, splenomegaly, or hepatomegaly. Posterior mediastinal or paravertebral masses of extramedullary hematopoietic tissue may be noted and signs of iron overload may also be present.

**Laboratory Findings**

The anemia is normocytic and is generally mild. Hemoglobin levels are lower in children than adults and range between 8 and 11 g/dL. The reticulocyte count, although inadequate, may appear to be normal or increased. Anisopoikilocytosis is noted and occasional basophilic stippling, as well as a few, sometimes binucleate, mature erythroblasts may be found on the peripheral smear. The bone marrow aspirate is normoblastic but hypercellular, with erythroid hyperplasia. In contrast to CDA I, there are many binucleate late polychromatic erythroblasts (10-35%) as well as a few that are multinucleate. Pseudo-Gaucher cells may be present. Electron micrographs show vesicles that are laden with endoplasmic reticulum proteins running beneath the plasma membrane. The pathognomonic finding in type II CDA is that the patient's RBCs lyse in acidified serum because of an immunoglobulin M antibody that recognizes an antigen present on CDA II cells but absent on normal cells. Type II CDA is also known by the acronym HEMPAS (hereditary erythroblastic multinuclearity with a positive acidified serum test) because it features both erythroblast multinuclearity and circulating RBCs that are sensitive to lysis by acidified normal serum. As this test is technically difficult, the diagnosis is usually made by analyzing red cell membrane proteins via sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). In CDAII there is a thinner band size and faster migration of erythrocyte anion transporter (EA1), or band 3, and band 4.5 proteins.

**Treatment**

Approximately 10% of patients will require red cell transfusions in infancy and childhood but rarely during adulthood. In contrast to type I CDA, splenectomy may provide hematologic improvement. Splenectomy does not prevent further iron overloading, even in those patients whose hemoglobin is normalized, presumably because of persistent ineffective erythropoiesis in the bone marrow. Like CDA I, secondary hemochromatosis is the most prominent long-term complication and should be approached as outlined above. Allogeneic bone marrow transplantation was successful when pursued in an adult with CDA II and β-thalassemia trait. Most patients can lead a normal life and have a normal life expectancy if complications and consequences are managed appropriately.

**TYPE III CONGENITAL DYSERYTHROPOIETIC ANEMIA**

Type III CDA is an extremely rare, ill-defined entity, manifested by a mild-to-moderate macrocytic anemia. It is inherited in an autosomal
Bibliography
At birth, normal full-term infants have higher hemoglobin (Hb) levels and larger red blood cells (RBCs) than do older children and adults. However, within the 1st wk of life, a progressive decline in Hb level begins and then persists for 6–8 wk. The resulting anemia is known as the **physiologic anemia of infancy**.

With the onset of respiration at birth, considerably more oxygen becomes available for binding to Hb, and, as a consequence, the Hb–oxygen saturation increases from 50% to 95% or more. There is also a gradual, normal developmental switch from fetal to adult Hb synthesis after birth that results in the replacement of high-oxygen-affinity fetal Hb with lower-affinity adult Hb, capable of delivering more oxygen to tissues. The increase in blood oxygen content and delivery results in the downregulation of erythropoietin (EPO) production, leading to suppression of erythropoiesis. Because there is no erythropoiesis, aged RBCs that are removed from the circulation are not replaced and the Hb level decreases. The Hb concentration continues to decline until tissue oxygen needs become greater than oxygen delivery. Normally, this point is reached between 8 and 12 wk of age, when the Hb concentration is about 11 g/dL. In healthy term infants, the nadir rarely falls below 10 g/dL. At this juncture, EPO production increases and erythropoiesis resumes. The supply of stored reticuloendothelial iron, derived from previously degraded RBCs, remains sufficient for this renewed Hb synthesis, even in the absence of dietary iron intake, until approximately 20 wk of age. In all, this “anemia” should be viewed as a physiologic adaptation to extrauterine life, reflecting the excess oxygen delivery relative to tissue oxygen requirements. There is no hematologic problem, and no therapy is required unless physiologic anemia of infancy is exacerbated by other ongoing processes.

A late **hyporegenerative anemia**, with absence of reticulocytes, can occur in infants with mild hemolytic disease of the newborn. The persistence of maternally derived anti-RBC antibodies in the infant’s circulation can lead to an ongoing low-grade hemolytic anemia that can exaggerate the physiologic anemia. Lower-than-expected Hb at the “physiologic” nadir has also been seen in infants after intrauterine or neonatal RBC transfusions. When infants are transfused with adult blood containing HbA, the associated shift of the oxygen dissociation curve facilitates oxygen delivery to the tissues. Accordingly, the definition of anemia and the need for transfusion should be based not only
on the infant’s Hb level, but also on oxygen requirements and the ability of circulating RBCs to release oxygen to the tissues.

Premature infants also develop a physiologic anemia, known as physiologic anemia of prematurity. The Hb decline is both more extreme and more rapid. Minimal Hb levels of 7-9 g/dL commonly are reached by 3-6 wk of age, and levels may be even lower in very small premature infants (see Chapter 103). The same physiologic factors at play in term infants are operative in preterm infants but are exaggerated. In premature infants, the physiologic Hb decline may be intensified by blood loss from repeated phlebotomies obtained to monitor ill neonates. Demands on erythropoiesis are further heightened by the premature infant’s shortened RBC life span (40-60 days) and the accelerated expansion of RBC mass that accompanies the premature baby’s rapid rate of growth. Nonetheless, plasma EPO levels are lower than would be expected for the degree of anemia, resulting in a suboptimal erythropoietic response. The reason for diminished EPO levels is not fully understood. During fetal life, EPO synthesis is handled primarily by the liver, whose oxygen sensor is relatively insensitive to hypoxia when compared to the oxygen sensor of the kidney. The developmental switch from liver to kidney EPO production is not accelerated by early birth, and thus the preterm infant must rely on the liver as the primary site for synthesis, leading to diminished responsiveness to anemia. An additional mechanism thought to contribute to diminished responsiveness to anemia is the diminished EPO metabolism. As the pronounced decline in Hb that occurs in many very low birthweight infants is associated with abnormal clinical signs, the “anemia of prematurity” is not considered to be benign and usually requires transfusions.

Some dietary factors, such as folic acid deficiency, can aggravate physiologic anemia. Unless there has been significant blood loss, iron stores should be sufficient to maintain erythropoiesis early on. Vitamin E deficiency does not play a role in anemia of prematurity. Breast milk and infant formulas provide adequate vitamin E.

**TREATMENT**

In the full-term infant, physiologic anemia requires no therapy beyond ensuring that the infant’s diet contains essential nutrients for normal hematopoiesis. In premature infants, an optimal Hb has not been established and is usually dictated by the infant’s overall clinical condition. Transfusions may be needed to maintain the Hb at what is considered safe for that child. Premature infants who are feeding well and growing normally rarely need transfusion unless iatrogenic blood loss has been significant. Although factors such as poor weight gain, respiratory difficulties, and abnormal heart rate have prompted transfusion, the beneficial effect has not been documented. Laboratory tests such as blood lactate, EPO, and mixed venous oxygen saturation have poor predictive value. Liberal and restrictive transfusion strategies have been compared in this population. A restrictive strategy does not increase infant morbidity or mortality. In addition, long-term neurodevelopmental outcomes have been found to be poorer in liberally transfused neonates. Late exposure to packed RBC may be related to the development of necrotizing enterocolitis, and early transfusions may be associated with the risk of intraventricular hemorrhage.

When transfusions are necessary, an RBC volume of 10-15 mL/kg is recommended. It is good practice to split units derived from a single donor so that sequential transfusions can be given as required and donor exposure can be minimized. In early preterm infants (weighing <1,250 g), the half-life of transfused RBCs is about 30 days. Delayed cord clamping or umbilical cord milking at birth results in fewer transfusions and a reduction in both intraventricular hemorrhage and necrotizing enterocolitis in preterm infants. Given the impact of phlebotomy losses during monitoring in the neonatal ICU, attention to reducing unnecessary blood draws also has been advocated.

Because premature infants are known to have low plasma EPO levels, recombinant human EPO may be an alternative to transfusion for the treatment of symptomatic preterm infants with anemia of prematurity. In early studies, it was unclear whether EPO reliably reduced donor exposures and reports of adverse effects, such as a possible increase in retinopathy of prematurity, further limited a willingness to use this expensive treatment. One study of preterm infants compared the weekly use of the long-acting agent darbepoetin to triweekly EPO or placebo. Supplemental iron, folate, and vitamin E were provided and the infants were transfused according to an established protocol. Those receiving either EPO or darbepoetin received half the number of transfusions and about half the donors compared with the placebo group. The incidence of mortality, retinopathy, and intracranial hemorrhage was no different between the groups. Nonetheless, this remains an area of controversy.

Bibliography

Megaloblastic anemia describes a group of disorders that are caused by impaired DNA synthesis. Red blood cells (RBCs) are larger than normal at every developmental stage, and there is maturational asynchrony between the nucleus and cytoplasm of erythrocytes. The delayed nuclear development becomes increasingly evident as cell divisions proceed. Myeloid and platelet precursors are also affected, and giant metamyelocytes and neutrophil bands are often present in the bone marrow. There is often an associated thrombocytopenia and leukopenia. The peripheral blood smear is notable for large, often oval, RBCs with increased mean corpuscular volume. Neutrophils are characteristically hypersegmented, with many having >5 lobes. Most cases of childhood megaloblastic anemia result from a deficiency of folic acid or vitamin B<sub>12</sub> (cobalamin), vitamins essential for DNA synthesis. Rarely, these anemias may be caused by inborn errors of metabolism. Megaloblastic anemias resulting from malnutrition are relatively uncommon in the United States, but are important worldwide (see Chapters 46 and 447).

### 454.1 Folic Acid Deficiency

Folic acid, or pteroylglutamic acid, consists of pteroic acid conjugated to glutamic acid. Biologically active folates are derived from folic acid and serve as 1-carbon donors and acceptors in many biosynthetic pathways. To form functional compounds, folates must be reduced to tetrahydrofolates in a process catalyzed by the enzyme dihydrofolate reductase. As such, they are essential for DNA replication and cellular proliferation. Like other mammals, humans cannot synthesize folate and depend on dietary sources, including green vegetables, fruits, and animal organs (e.g., liver, kidney). Folates are heat labile and water soluble; consequently, boiling or heating folate sources leads to decreased amounts of vitamin. Naturally occurring folates are in a polyglutamated form that is less efficiently absorbed than the monoglutamate species (i.e., folic acid). Dietary folate polyglutamates are hydrolyzed to simple folates that are absorbed primarily in the proximal small intestine by a specific carrier-mediated system. Folates travel in the bloodstream and are taken up in cells primarily in the form of unconjugated methylenetetrahydrofolate, which is subsequently reconjugated (polyglutamated) in the cell. There is an active enterohepatic circulation. Although rare, megaloblastic anemia as a consequence of folate deficiency has its peak incidence at 4-7 mo of age, somewhat earlier than iron-deficiency anemia, although both conditions may be present concomitantly in infants with poor nutrition.
ETIOLOGY
Folic acid deficiency can occur as a consequence of inadequate folate intake, decreased folate absorption, or acquired and congenital disorders of folate metabolism or transport.

Inadequate Folate Intake
In the United States, anemia caused by insufficient folate intake usually occurs in the context of increased vitamin requirements associated with pregnancy, periods of accelerated growth, and/or chronic hemo-
lisis. Folate requirements increase markedly during pregnancy, in part to meet fetal needs, and deficiencies are common in mothers, particu-
larly those who are poor or malnourished. Folate supplementation is recommended from the start of pregnancy to prevent neural tube defects and to meet the needs of the developing fetus. Fortunately, folate-deficient mothers generally do not give birth to infants with clinical folate deficiency because there is selective transfer of folate to the fetus via placental folate receptors. Rapid growth after birth increases demands for folic acid and infants who are premature or ill and those with certain hemolytic disorders will have particularly high folate requirements. Human breast milk, infant formulas, and pasteur-
ized cow's milk provide adequate amounts of folic acid. Goat's milk is deficient, and supplementation must be given when it is the child's main food. Unless supplemented, powdered milk may also be a poor source of folic acid.

Malnutrition is the most common cause of folate deficiency in older children, and those with hemoglobinopathies, infections, and/or mal-
absorption are at increased risk. Because body stores of folate are limited, deficiency can develop quickly in malnourished individuals. On a folate-free diet, megaloblastic anemia will occur after 2-3 mo.

Decreased Folate Absorption
Malabsorption caused by chronic diarrheal states or diffuse inflamma-
tory disease can lead to folate deficiency. In both situations, some of the decreased folate absorption may be caused by impaired folate con-
jugase activity. Chronic diarrhea also interferes with the enterohepatic circulation of folate, thereby enhancing folate losses because of rapid intestinal passage. Megaloblastic anemia because of folic acid defi-
ciency can occur in celiac disease or chronic infectious enteritis and in association with enteroinvasive fistulas. Previous intestinal surgery is another potential cause of decreased folate absorption.

Certain anticonvulsant drugs (e.g., phenytoin, primidone, pheno-
barbital) can impair folic acid absorption, and many patients treated with these drugs have low serum levels. Frank megaloblastic anemia is rare and readily responds to folic acid therapy, even when administra-
tion of the offending drug is continued. Alcohol abuse also is associ-
ated with folate malabsorption.

Congenital Abnormalities in Folate Transport and Metabolism
Inborn errors of folate transport or metabolism are rare but can be life-threatening. Those associated with megaloblastic anemia include hereditary folate malabsorption and certain extremely uncommon enzyme deficiencies.

Hereditary folate malabsorption (HFM) is an autosomal recessive disorder that is linked to several loss-of-function mutations in the SLC46A1 gene encoding the protein-coupled folate transporter. HFM is associated with an inability to absorb folic acid, 5-tetrahydrofolate, 5-methyltetrahydrofolate, or 5-formyltetrahydrofolate (folinic acid). It can become apparent at 2-6 mo of age with megaloblastic anemia and other deficits, including infections and diarrhea. Neurologic abnor-
malities, attributable to folate deficiency in the central nervous system, include seizures, developmental delay, and mental retardation. Folate transport is impaired in both the intestine and at the brain's choroid plexus. Serum and cerebrospinal fluid (CSF) folate levels are very low, with a loss of the normal 3:1 ratio of CSF to serum folate.

Treatment, specifically in the context of HFM, usually involves par-
enteral folate, although oral administration has been useful in some cases. Reduced folates are more effective than folic acid. Folate suffi-
ciency should be maintained in both the blood and the CSF so as to avoid important complications. The megaloblastic anemia of HFM can be reversed with relatively low levels of serum folate, but adequate CSF levels may be quite difficult to achieve, and very large folate doses may be needed.

Functional methionine synthase deficiency may result from muta-
tions affecting the function of methionine synthase reductase or methi-
onine synthase. These disorders are autosomal recessive and are characterized not only by megaloblastic anemia, but also by cerebral atrophy, nystagmus, blindness, and altered muscle tone. Both respond to hydroxocobalamin plus betaine with variable clinical success. Dihy-
drofolate reductase deficiency is extremely rare and is associated with homozygous mutations in the DHFR gene. Clinical symptoms include megaloblastic anemia and neurologic manifestations. Although meth-
ylenetetrahydrofolate (MTHFR) deficiency is the most common inborn error of folate metabolism and severe cases can produce a number of neurologic and vascular complications, there is no associ-
ated megaloblastic anemia.

Drug-Induced Abnormalities in Folate Metabolism
A number of drugs have anti–folic acid activity as their primary pharmacologic effect and regularly produce megaloblastic anemia. Methotrexate binds to dihydrofolate reductase and prevents forma-
tion of tetrahydrofolate, the active form of folate. Pyrimethamine, used in the therapy of toxoplasmosis, and trimethoprim, used for treatment of various infections, can induce folic acid deficiency and, occasionally, megaloblastic anemia. Therapy with folic acid (5-formyltetrahydrofolate) is usually beneficial.

CLINICAL MANIFESTATIONS
Besides the clinical features associated with anemia, folate-deficient infants and children may manifest irritability, chronic diarrhea, and/or poor weight gain. Hemorrhages from thrombocytopenia may occur in advanced cases. Congenital folate malabsorption and other rare etiologies of folate deficiency may be further associated with hypogam-
agalobulinemia, severe infections, failure to thrive, neurologic abnor-
malities, and cognitive delays.

LABORATORY FINDINGS
The anemia is macrocytic (mean corpuscular volume >100 FL). Varia-
tions in RBC shape and size are common (see Fig. 447-4B in Chapter 447). The reticulocyte count is low, and nucleated RBCs with megaloblastic morphology are often seen in the peripheral blood. Neutropenia and thrombocytopenia may be present, particularly in patients with long-standing and severe deficiencies. The neutrophils are large, some with hypersegmented nuclei. The bone marrow is hypercellular because of erythroid hyperplasia, and megaloblastic changes are prominent. Large, abnormal neutrophilic forms (giant metamyelocytes) with cyto-
plasmic vacuolation are also seen.

Normal serum folic acid levels are 5-20 ng/mL; with deficiency, levels are <3 ng/mL. Levels of RBC folate are a better indicator of chronic deficiency. The normal RBC folate level is 150-600 ng/mL of packed cells. Levels of iron and vitamin B12 in serum usually are normal or elevated. Serum activity of lactate dehydrogenase, a marker of inef-
factive erythropoiesis, is markedly elevated.

TREATMENT
When the diagnosis of folate deficiency is established, folic acid may be administered orally or parenterally at 0.5-1.0 mg/day. If the specific diagnosis is in doubt, smaller doses of folate (0.1 mg/day) may be used for 1 wk as a diagnostic test, because a hematologic response can be expected within 72 hr. Doses of folate >0.1 mg can correct the anemia of vitamin B12 deficiency but might aggravate any associated neurologic abnormalities. In most medical settings in developed countries, this therapeutic trial to distinguish the different causes of megaloblastic anemia is rarely necessary because vitamin B12 and folate blood levels are usually readily available. Folic acid therapy (0.5-1.0 mg/day) should be continued for 3-4 wk until a definite hematologic response has occurred. Maintenance therapy with a multivitamin (containing 0.2 mg of folate) is adequate. As described above, very high doses of
folic acid may be required in the setting of HFM. Transfusions are indicated only when the anemia is severe or the child is very ill.

Bibliography is available at Expert Consult.

**454.2 Vitamin B₁₂ (Cobalamin) Deficiency**
Norma B. Lerner

Vitamin B₁₂, a generic term encompassing all biologically active cobalamins, is a water-soluble vitamin with a central, functional cobalt atom and a planar corrin ring. Methylcobalamin and adenosylcobalamin are the metabolically active derivatives, serving as cofactors in 2 essential metabolic reactions, namely methylation of homocysteine to methionine (via methionine synthase) and conversion of methyl-malonyl-Coenzyme A (CoA) to succinyl CoA (via l-methyl-malonyl-CoA mutase). The products and by-products of these enzymatic reactions are critical to DNA, RNA, and protein synthesis.

Cobalamin is synthesized exclusively by microorganisms and humans must rely on dietary sources (animal products including meat, eggs, fish, and milk) for their needs. Unlike folate, older children and adults have sufficient vitamin B₁₂ stores to last 3-5 yr. In young infants born to mothers with low vitamin B₁₂ stores, clinical signs of cobalamin deficiency can become apparent in the first 6-18 mo of life.

**METABOLISM**
Under normal circumstances, cobalamin is released from food protein in the stomach via peptic digestion. Cobalamin then binds to haptocorrin (HC), a salivary glycoprotein. This complex moves into the duodenum, where HC is digested by pancreatic proteases and cobalamin is liberated. Cobalamin then binds to intrinsic factor (IF), another glycoprotein that is produced by gastric parietal cells. The cobalamin-IF complex subsequently enters mucosal cells of the distal ileum by receptor-mediated endocytosis. The IF-cobalamin receptors are composed of a complex of 2 proteins, cubulin (CUBN) and amnionless (AMN), collectively known as cubam. Following internalization into enterocytes, IF is degraded in the lysosome and cobalamin is released. The transporter ABCC1 (also known as MRPI) exports cobalamin bound to the transport protein transcobalamin (TC), out of the cell. In the bloodstream, cobalamin is associated with either TC (approximately 20%) or HC. TC mediates B₁₂ transport across cells after complexing with the TC receptor, which is internalized in the lysosome. Lysosomal degradation of TC releases cobalamin which remains in the cell where it is further processed. Two distinct membrane proteins transport cobalamin across the lysosomal membrane into the cytoplasm. There cobalamins are processed to a common intermediate that can be allocated to the methylcobalamin and adenosylcobalamin synthesis pathways to meet cellular needs. It is postulated that the MMACHC protein, a product of the cobalamin (Cbl) C locus, accepts the cobalamins exiting the lysosome. A definitive role for HC is yet to be established, but it has been suggested that it plays a role in B₁₂ storage.

**ETIOLOGY**
Vitamin B₁₂ deficiency can result from inadequate dietary intake of Cbl, lack of IF, impaired intestinal absorption of IF-Cbl, or absence of vitamin B₁₂ transport protein.

**Inadequate Vitamin B₁₂ Intake**
B₁₂ deficiency in infants is most often nutritional, resulting from low B₁₂ levels in the breast milk of B₁₂-deficient mothers. Associated megaloblastic anemia often appears during the 1st yr of life. Maternal deficiency may be caused by pernicious anemia or gastrointestinal disorders such as Helicobacter pylori infection, celiac disease, Crohn disease, or pancreatic insufficiency. Previous gastric bypass surgery, treatment with proton pump inhibitors, or inadequate intake from a strict vegetarian diet has also been implicated. Fortunately, as a result of active placental Cbl transport in utero, most children of deficient mothers maintain Cbl levels sufficient to support adequate prenatal development. Such infants are born with low stores, the depletion of which is associated with a gradual onset of clinical manifestations. B₁₂ replacement often results in rapid improvement, but the longer the deficient period, the greater the likelihood of permanent disabilities. Neonatal screening programs may detect maternal–neonatal nutritional B₁₂ deficiency as a result of an increase in propionyl carnitine, but there is higher sensitivity using a measurement of methylmalonic acid. In high-income countries, dietary deficiency during childhood or adolescence is infrequent but can result, as in adults, from strict vegetarian or vegan diet. Daily requirements range from 0.4-2.4 µg.

**Impaired Absorption**
Gastric surgery or medications that impair gastric acid secretion may result in IF deficiency, leading to decreased vitamin B₁₂ absorption. Pancreatic insufficiency can also lead to Cbl deficiency as a consequence of impaired cleavage and IF complex formation. Patients with neonatal necrotizing enterocolitis, inflammatory bowel disease, celiac disease, or surgical removal of the terminal ileum, may also have impaired absorption of vitamin B₁₂. An overgrowth of intestinal bacteria within diverticula or duplications of the small intestine can cause vitamin B₁₂ deficiency by consumption of (or competition for) the vitamin or by splitting of its complex with IF. In these cases, hematologic response can follow appropriate antibiotic therapy. In endemic areas, when the fish tapeworm Diphyllobothrium latum infests the upper small intestine, similar mechanisms may be operative. When megaloblastic anemia occurs in such situations, the serum vitamin B₁₂ level is low and the gastric fluid contains IF.

**Hereditary intrinsic factor deficiency (HIFD)** is a rare autosomal recessive disorder caused by a variety of mutations in the IF gene that produce a lack of gastric IF or a functionally abnormal IF. It differs from typical adult pernicious anemia in that gastric acid is secreted normally and the stomach is histologically normal. It is not associated with antibodies or endocrine abnormalities. Unlike Imerslund-Grasbeck syndrome (described below), hereditary IF deficiency is only occasionally associated with proteinuria. Symptoms become prominent at an early age (6-24 mo), consistent with exhaustion of vitamin B₁₂ stores acquired in utero. As the anemia becomes severe, weakness, irritability, anorexia, and listlessness occur. The tongue is smooth, red, and painful. Neurologic manifestations include ataxia, paresthesias, hyporeflexia, Babinski responses, and clonus. Oral vitamin B₁₂ is usually ineffective and lifelong parenteral (IM) Cbl should be used to bypass the absorption defect. The natural form, hydroxocobalamin (OHcBl) is believed to be more effective than the synthetic form, cyanocobalamin (CNCbl). In one retrospective study involving patients with HIFD and Imerslund-Grasbeck syndrome, patients with acute and severe anemia were initially treated with 1 mg of IM OHcBl daily until reticulocyte recovery after which dosing was spaced to once a week. Those without severe anemia were treated with weekly IM OHcBl or CNCbl. With cautious monitoring, all patients were ultimately safely maintained on a schedule of 1 mg of IM OHcBl or CNCbl every 6 mo.

**Imerslund-Grasbeck syndrome** is a rare, recessively inherited pediatric disorder resulting in selective vitamin B₁₂ malabsorption in the ileum, and consequent vitamin B₁₂ deficiency. It usually becomes clinically apparent within the first 6 yr of life. In addition to megaloblastic anemia, the patient may also have neurologic defects (such as hypotonia, developmental delay, brain atrophy, movement disorders, and dementia) and/or proteinuria. Patients carry mutations in either CUBN or AMN, proteins that form the cubam receptor for the ileal IF-Cbl complex. Because CUBN is also a key receptor for protein reabsorption in the kidney, impaired expression at this site results in associated proteinuria. The disease can be fatal if it remains untreated. Early diagnosis and treatment with IM Cbl (see treatment for HIFD above) will reverse the hematologic and neurologic abnormalities. Proteinuria does not respond to therapy.

**Classic pernicious anemia** (autoimmune gastritis) usually occurs in older adults but can rarely affect children. This disorder (juvenile pernicious anemia) usually presents during adolescence. In such cases,
Bibliography

the disease is associated with various detectable antibodies, including those against IF and the hydrogen potassium adenosine triphosphatase pump in gastric parietal cells. These children can have additional immunologic abnormalities, cutaneous candidiasis, hypoparathyroidism, and other endocrine deficiencies. There may be atrophy of the gastric mucosa and achlorhydria. Parenteral vitamin B₁₂ should be administered regularly.

**Absence of Vitamin B₁₂ Transport Protein**
TC deficiency is a rare cause of megaloblastic anemia. A congenital deficiency is inherited as an autosomal recessive condition resulting in a failure to absorb and transport vitamin B₁₂. Most patients lack TC but some have functionally defective forms. This disorder usually manifeststhe in first weeks of life. Characteristically, there is failure to thrive, diarrhea, vomiting, glossitis, neurologic abnormalities, and megaloblastic anemia. The diagnosis can be difficult given that total serum vitamin B₁₂ levels are often normal because approximately 80% of serum Cbl is bound to HC. The diagnosis is suggested by the presence of severe megaloblastic anemia in the face of normal folate levels and no evidence of any other inborn errors of metabolism. Plasma homocysteine and/or methylmalonic acid levels are elevated. A definitive diagnosis is made by measuring plasma TC. The serum vitamin B₁₂ levels must be kept high in order to force enough Cbl into cells to allow normal function. Oral Cbl (CNcBl or OHcBl) 500-1,000 µg twice a wk, or IM OHCbl 1,000 µg per wk, may be used for initial therapy. Symptoms and laboratory studies should be monitored and doses adjusted, as needed.

**Inborn Errors of Cobalamin Metabolism**
The conversion of Cbl to methylcobalamin (MeCbl) and adenosylcobalamin (AdoCbl) involves a number of steps, abnormalities of which have been tied to several distinct alphabetically labeled disorders. In CblE and CblG, defective N5-methyltetrahydrofolate-homocysteine methyltransferase fails to produce MeCbl. Patients present in infancy with megaloblastic anemia, vomiting, and mental retardation, and are found to have homocystinuria and hyperhomocystinemia. They do not have methylmalonic aciduria or methylmalonic acidemia. They show good response to CNcBl. AdoCbl and MeCbl are both affected by CblC (the most common of the Cbl inborn errors), CblD, and CblF. Patients can present in early infancy through adolescence. Newborns have lethargy, failure to thrive, and neurologic problems. Older patients may present with neurologic difficulties, dementia, and psychological problems. Megaloblastic anemia occurs in about half the cases. Patients have elevations of homocysteine and methylmalonic acid in both urine and blood. Affected individuals respond partially to OHcBl or CNcBl. CblA, CblB, and CblH are associated with methylmalonic aciduria and a variety of serious symptoms, but megaloblastic anemia is absent.

**CLINICAL MANIFESTATIONS**
Children with Cbl deficiency often present with nonspecific manifestations such as weakness, lethargy, feeding difficulties, failure to thrive, and irritability. Other common findings include pallor, glossitis, vomiting, diarrhea, and icterus. Neurologic symptoms can include parasthesia, sensory deficits, hypotonia, seizures, developmental delay, developmental regression, and neuropsychiatric changes. Neurologic problems from vitamin B₁₂ deficiency may occur in the absence of any hematologic abnormalities.

**LABORATORY FINDINGS**
The hematologic manifestations of folate and Cbl deficiency are identical. The anemia resulting from Cbl deficiency is macrocytic, with prominent macro-ovalocytosis of the RBCs (see Fig. 447-2 in Chapter 447). The neutrophils may be large and hypersegmented. In advanced cases, neutropenia and thrombocytopenia can occur, simulating aplastic anemia or leukemia. Serum vitamin B₁₂ levels are low, and the serum concentrations of methylmalonic acid and homocysteine are usually elevated. Concentrations of serum iron and serum folic acid are normal or elevated. Serum lactate dehydrogenase activity is markedly increased, a reflection of ineffective erythropoiesis. Moderate elevations of serum bilirubin levels (2-3 mg/dL) also may be found. Excessive excretion of methylmalonic acid in the urine (normal, 0-3.5 mg/24 hr) is a reliable and sensitive index of vitamin B₁₂ deficiency.

**DIAGNOSIS**
A comprehensive medical history is essential to the clinical recognition of possible Cbl deficiency. Information regarding clinical symptoms, dietary history, diseases, surgeries, or medications is likely to provide important clues. The physical exam may reveal relevant findings such as irritability, pallor, or specific neurologic symptoms. Screening laboratory findings (described above) offer important information but more focused testing will be required to confirm a diagnosis of vitamin B₁₂ deficiency and its cause. Cbl deficiency is usually identified by measuring total or TC bound vitamin B₁₂ in the blood. Although an extremely low level is generally diagnostic, this may not be the case, and false negatives and positives are reportedly common using currently available assays. As a result, it is wise not to discount vitamin B deficiency, particularly in the face of clinical symptoms, macrocytic anemia, an abnormal blood smear, and a normal folate level. In non-treated patients, methylmalonic acid and total homocysteine levels are often helpful as they are markedly elevated in the majority of those with clinical signs of B₁₂ deficiency. Excessive excretion of methylmalonic acid in the urine (normal: 0-3.5 mg/24 hr) is also a sensitive index of vitamin B₁₂ deficiency. Although modest increases occur with renal failure, elevated methylmalonic acid is otherwise quite specific for vitamin B₁₂ deficiency. Notably, however, serum homocysteine is also elevated in folate deficiency, homocystinuria, and renal failure. If B₁₂ deficiency has been confirmed and there is no evidence of inadequate dietary intake or, in the case of an infant, inadequate maternal B₁₂, malabsorption should be investigated. In the past, the Schilling test, a measure of Cbl absorption, was the gold standard. The test is no longer available and there is currently no comparable replacement for it. Anti–IF antibodies and anti–parietal cell antibodies are useful for the diagnosis of pernicious anemia. Measurement of IF and help from more specialized laboratories may be required for less common disorders.

**TREATMENT**
Treatment regimens in children have not been well studied. The cause of vitamin B₁₂ deficiency should ultimately dictate treatment dosage as well as the duration of therapy. Dose adjustments should be made in response to clinical status and laboratory values. The physiologic requirement for vitamin B₁₂ is about 1-3 µg/day. Hematologic responses have been observed with small doses, indicating that administration of a minidose may be used as a therapeutic test when the diagnosis of vitamin B₁₂ deficiency is in doubt or in circumstances where the anemia is severe and higher initial doses might result in severe metabolic disturbances.

**454.3 Other Rare Megaloblastic Anemias**
Norma B. Lerner

Orotic aciduria is a rare autosomal recessive disorder that usually appears in the 1st yr of life and is characterized by growth failure, developmental retardation, megaloblastic anemia, and increased urinary excretion of orotic acid (see Chapter 89). This defect is the most common metabolic error in the de novo synthesis of pyrimidines and therefore affects nucleic acid synthesis. The usual form of hereditary orotic aciduria is caused by a deficiency (in all body tissues) of orotidine-5-phosphate decarboxylase, 2 sequential enzymatic steps in pyrimidine nucleotide synthesis. The diagnosis is suggested by the presence of severe megaloblastic anemia with normal serum B₁₂ and folate levels and no evidence of TC deficiency. A presumptive diagnosis is made by finding increased urinary orotic acid. However, confirmation of the diagnosis requires assay of the transferase and decarboxylase enzymes in the patient's
**Bibliography**

erythrocytes. Physical and mental retardation often accompany this condition. The anemia is refractory to vitamin B$_{12}$ or folic acid, but responds promptly to administration of uridine.

**Thiamine-responsive megaloblastic anemia** (Rogers syndrome) is a very rare autosomal recessive disorder characterized by megaloblastic anemia, sensorineural deafness, and diabetes mellitus. Congenital heart defects, arrhythmias, visual problems, short stature, tri-lineage myelodysplasia, and strokes are also described. Thiamine-responsive megaloblastic anemia usually presents in infancy but may occasionally develop in childhood and adolescence and occurs in several ethnically distinct populations. The bone marrow is characterized not only by megaloblastic changes but also by ringed sideroblasts. The defect is caused by mutations in the *SCL19A2* gene on chromosome 1, which encodes a high-affinity plasma membrane thiamine transporter. Continuous thiamine supplementation usually reverses the anemia and diabetes but not existing hearing defects.

Bibliography
Iron deficiency is the most widespread and common nutritional disorder in the world. It is estimated that 30% of the global population has iron-deficiency anemia, and most of them live in developing countries. In the United States, 9% of children ages 12-36 mo are iron deficient, and 30% of this group progresses to iron-deficiency anemia.

A full-term newborn infant contains about 0.5 g of iron, compared to 5 g of iron in adults. This change in quantity of iron from birth to adulthood means that an average of 0.8 mg of iron must be absorbed each day during the first 15 yr of life. A small additional amount is necessary to balance normal losses of iron by shedding of cells. It is therefore necessary to absorb approximately 1 mg daily to maintain positive iron balance in childhood. Because <10% of dietary iron is usually absorbed, a dietary intake of 8-10 mg of iron daily is necessary to maintain iron levels. During infancy, when growth is most rapid, the approximately 1 mg/L of iron in cow's and breast milk makes it difficult to maintain body iron. Breastfed infants have an advantage because they absorb iron 2-3 times more efficiently than infants fed cow's milk.

**ETIOLOGY**

Most iron in neonates is in circulating hemoglobin. As the relatively high hemoglobin concentration of the newborn infant falls during the first 2-3 mo of life, considerable iron is recycled. These iron stores are usually sufficient for blood formation in the first 6-9 mo of life in term infants. Stores are depleted sooner in low-birthweight infants or infants with perinatal blood loss because their iron stores are smaller. Delayed clamping of the umbilical cord can improve iron status and reduce the risk of iron deficiency, whereas early clamping (<30 sec) puts the infant at risk for iron deficiency. Dietary sources of iron are especially important in these infants. In term infants, anemia caused solely by inadequate dietary iron usually occurs at 9-24 mo of age and is relatively uncommon thereafter. The usual dietary pattern observed in infants and toddlers with nutritional iron-deficiency anemia in developed countries is excessive consumption of cow's milk (low iron content, blood loss from milk protein colitis) in a child who is often overweight.

Worldwide, undernutrition is usually responsible for iron deficiency. Blood loss must be considered as a possible cause in every case of iron-deficiency anemia, particularly in older children and adolescents.

Chronic iron-deficiency anemia from occult bleeding may be caused by a lesion of the gastrointestinal (GI) tract, such as peptic ulcer, Meckel diverticulum, polyp, hemangioma, or inflammatory bowel disease. Infants can have chronic intestinal blood loss induced by exposure to whole cow's milk protein. This GI reaction is not related to enzymatic abnormalities in the mucosa, such as lactase deficiency, or to an immunoglobulin E–associated milk allergy. Involved infants characteristically develop anemia that is more severe and occurs earlier than would be expected simply from an inadequate intake of iron. The ongoing loss of blood in the stools can be prevented either by breastfeeding or by delaying the introduction of whole cow's milk in the 1st yr of life and then limiting the quantity to <24 oz/24 hr. Unrecognized blood loss also can be associated with chronic diarrhea and, rarely, with pulmonary hemosiderosis. In developing countries, infections with hookworm, *Trichuris trichiura*, *Plasmodium*, and *Helicobacter pylori* often contribute to iron deficiency. Celiac disease and giardiasis may interfere with iron absorption.

Approximately 2% of adolescent girls have iron-deficiency anemia, largely as a result of their adolescent growth spurt and menstrual blood loss. The highest risk of iron-deficiency anemia (>30%) is among teenagers who are or have been pregnant.

**CLINICAL MANIFESTATIONS**

Most children with iron deficiency are asymptomatic and are identified by recommended laboratory screening at 12 mo of age, or sooner if at high risk. Pallor is the most important clinical sign of iron deficiency but is not usually visible until the hemoglobin falls to 7-8 g/dL. It is most readily noted as pallor of the palms, palmar creases, nail beds, or conjunctivae. Parents often fail to note the pallor because of the typical slow decline of hemoglobin over time. Often a visiting friend or relative is the first to notice. In mild to moderate iron deficiency (i.e., hemoglobin levels of 6-10 g/dL), compensatory mechanisms, including increased levels of 2,3-diphosphoglycerate and a shift of the oxygen dissociation curve, may be so effective that few symptoms of anemia aside from mild irritability are noted. When the hemoglobin level falls to <5 g/dL, irritability, anorexia, and lethargy develop, and systolic flow murmurs are often heard. As the hemoglobin continues to fall, tachycardia and high output cardiac failure can occur.

Iron deficiency has nonhematologic systemic effects. Both iron deficiency and iron-deficiency anemia are associated with impaired neurocognitive function in infancy. There is also an association of iron-deficiency anemia and later, possibly irreversible, cognitive defects. Although there is support for iron deficiency with or without anemia causing these defects, it has not been established unequivocally. Some studies suggest an increased risk of seizures, strokes, breathholding spells in children, and exacerbations of restless leg syndrome in adults. Given the frequency of iron deficiency and iron-deficiency anemia and the potential for adverse neurodevelopmental outcomes, minimizing the incidence of iron deficiency is an important goal.

Other nonhematologic consequences of iron deficiency include pica, the desire to ingest nonnutritive substances, and *pagophagia*, the desire to ingest ice. The pica can result in the ingestion of lead-containing substances and result in concomitant *plumbism* (see Chapter 721).

**LABORATORY FINDINGS**

In progressive iron deficiency, a sequence of biochemical and hematologic events occurs (Tables 455-1 and 455-2). First, tissue iron stores are depleted. This depletion is reflected by reduced serum ferritin, an iron-storage protein, which provides an estimate of body iron stores in the absence of inflammatory disease. Next, serum iron levels decrease, the iron-binding capacity of the serum (serum transferrin) increases, and the transferrin saturation falls below normal. As iron stores decrease, iron becomes unavailable to complex with protoporphyrin to form heme. Free erythrocyte protoporphyrins accumulate, and hemoglobin synthesis is impaired. At this point, iron deficiency progresses to iron-deficiency anemia. With less available hemoglobin in each cell, the red cells become smaller and varied in size. The variation in red cell size is measured by an increasing red cell distribution width. This is followed by a decrease in mean corpuscular volume and mean corpuscular hemoglobin. Developmental changes in mean corpuscular
volume require the use of age-related standards for recognizing microcytosis (see Table 447-1). The red blood cell count also decreases. The reticulocyte percentage may be normal or moderately elevated, but absolute reticulocyte counts indicate an insufficient response to the degree of anemia. The blood smear reveals hypochromic, microcytic red cells with substantial variation in cell size. Elliptocytic or cigar-shaped red cells are often seen (Fig. 455-1). Detection of increased soluble transferrin receptor and decreased reticulocyte hemoglobin concentration provide very useful and early indicators of iron deficiency, but their availability is more limited.

White blood cell count is normal, and thrombocytosis is often present. Thrombocytopenia is occasionally seen with iron deficiency,
Iron deficiency is best prevented to avoid both its systemic manifestations and the anemia. Breastfeeding should be encouraged, with the addition of supplemental iron at 4 mo of age. Infants who are not breastfed should only receive iron-fortified formula (12 mg of iron per liter) for the first year, and thereafter cow’s milk should be limited to <20-24 oz daily. This approach encourages the ingestion of foods richer in iron and prevents blood loss as a result of cow’s milk–induced enteropathy.

When these preventive measures fail, routine screening helps prevent the development of severe anemia. Routine screening using hemoglobin or hematocrit is done at 12 mo of age, or earlier if at 4 mo of age the child is assessed to be at high risk for iron deficiency. Thereafter screening should continue if risk factors are identified.

TREATMENT

The regular response of iron-deficiency anemia to adequate amounts of iron is a critical diagnostic and therapeutic feature (Table 455-4). Oral administration of simple ferrous salts (most often ferrous sulfate) provides inexpensive and effective therapy. There is no evidence that the addition of any trace metal, vitamin, or other hematinic substance significantly increases the response to simple ferrous salts. Aside from the unpleasant taste of iron, intolerance to oral iron is uncommon in young children. In contrast, older children and adolescents sometimes have GI complaints. The therapeutic dose should be calculated in terms of elemental iron. A daily total dose of 3-6 mg/kg of elemental iron in 3 divided doses is adequate, with the higher dose used in more severe cases. The maximum dose would be 150-200 mg of elemental iron daily. Ferrous sulfate is 20% elemental iron by weight and is ideally given between meals with juice, although this timing is usually not critical with a therapeutic dose. Parenteral iron preparations are only used when malabsorption is present or when compliance is poor, because oral therapy is otherwise as fast, as effective, much less expensive and less toxic. When necessary, parenteral iron sucrose, ferric carboxymaltose, and ferric gluconate complex have a lower risk of serious reactions than iron dextran, although only the latter is FDA approved for use in children.

Iron therapy may increase the virulence of malaria and certain Gram-negative bacteria, particularly in developing countries. Iron overdose is associated with Yersinia infection.
In addition to iron therapy, dietary counseling is usually necessary. Excessive intake of milk, particularly cow’s milk, should be limited. Iron deficiency in adolescent girls secondary to menorrhagia is treated with iron and menstrual control with hormone therapy (see Chapter 116.2).

If the anemia is mild, the only additional study is to repeat the blood count approximately 4 wk after initiating therapy. At this point, the hemoglobin has usually risen by at least 1-2 g/dL and has often normalized. If the anemia is more severe, earlier confirmation of the diagnosis can be made by the appearance of a reticulocytosis usually within 48-96 hr of instituting treatment. The hemoglobin will then begin to increase 0.1-0.4 g/dL per day depending on the severity of the anemia. Iron medication should be continued for 2-3 mo after blood values normalize to reestablish iron stores. Good follow-up is essential to ensure a response to therapy. When the anemia responds poorly or not at all to iron therapy, there are multiple considerations, including diagnoses other than iron deficiency (see Table 455-3).

Because a rapid hematologic response can be confidently predicted in typical iron deficiency, blood transfusion is rarely necessary. It should only be used when heart failure is imminent or if the anemia is severe with evidence of substantial ongoing blood loss. Unless there is active bleeding, transfusions must be given slowly to avoid precipitating or exacerbating congestive heart failure.

Chapter 455  Iron-Deficiency Anemia

Bibliography

DEFECTS OF IRON METABOLISM

Rare microcytic anemias may be associated with defects in iron trafficking and regulation. Most are inherited and usually identified in childhood. They include defects of iron absorption, transport, utilization, and recycling. A defect of iron absorption is iron refractory iron deficiency anemia. This defect of transmembrane proteins causes a remarkably severe microcytosis out of proportion to the degree of anemia. This is an autosomal recessive disease due to loss of function mutations in TMPRSS6. In most cases, it is unresponsive to oral iron and partially responsive to intravenous iron. Defects of iron recycling include aceruloplasminemia, in which iron cannot be appropriately transported from macrophages to plasma.

Defects of mitochondrial iron utilization are a diverse group of acquired and inherited defects known as sideroblastic anemias. Impaired heme synthesis leads to retention of iron within the mitochondria of marrow red blood cells (RBCs). The perinuclear distribution of mitochondria results in a pattern of iron staining surrounding the nucleus. These are ringed sideroblasts (Fig. 456-1), which are distinct from the more diffuse cytoplasmic distribution of iron in normal RBC precursors. The anemia is characterized by hypochromic microcytic RBCs mixed with normal RBCs, so the complete blood cell count indicates a very high RBC distribution width. The serum iron concentration usually is elevated, and the transferrin saturation of iron is increased.

Congenital sideroblastic anemia is usually an X-linked disorder and is most commonly a result of mutations in erythrocytic isozyme 5-aminolevulinic acid synthetase, the rate-limiting enzyme reaction in heme synthesis. An important cofactor for 5-aminolevulinic acid synthetase is pyridoxal phosphate. Several of these mutations occur near the binding site for pyridoxal phosphate. Severe anemia is recognized in infancy or early childhood, whereas milder cases might not become apparent until early adulthood or later. Clinical findings include pallor, icterus, and moderate splenomegaly and/or hepatomegaly. The severity of the anemia varies such that some patients require no therapy and others need regular RBC transfusions. A subset of patients with hereditary sideroblastic anemia manifests a hematologic response to pharmacologic doses of pyridoxine. Iron overload as manifested by elevated serum ferritin, elevated serum iron, and increased transferrin saturation is a major complication of this disorder. Clinical evidence of iron overload (e.g., diabetes mellitus, liver dysfunction) may be found in some patients who have little or no anemia. Stem cell transplantation has been used to treat affected children who are dependent on RBC transfusions.

A unique variant of congenital sideroblastic anemia is Pearson syndrome (see Chapter 449), but the anemia is usually macrocytic and not microcytic. Another rare variant of sideroblastic anemia is due to mutations in TRNT1 and manifests with developmental delay, recurrent fevers, and immunodeficiency in addition to anemia.

Acquired sideroblastic anemias can be triggered by drugs and toxins that disturb mitochondrial iron metabolism, including lead and isoniazid. The acquired neoplastic sideroblastic syndromes seen in adults are very rare in children.

Bibliography
Hemolytic Anemias

Hemolytic Anemias is defined as the premature destruction of red blood cells (RBCs) (a shortened RBC life span). Anemia results when the rate of destruction exceeds the capacity of the marrow to produce RBCs. Normal RBC survival time is 110-120 days (half-life: 55-60 days), and thus, approximately 0.85% of the most senescent RBCs are removed and replaced each day. During hemolysis, RBC survival is shortened, the RBC count falls, erythropoietin is increased, and the stimulation of marrow activity results in heightened RBC production, reflected in an increased percentage of reticulocytes in the blood. Thus, hemolysis should be suspected as a cause of anemia if an elevated reticulocyte count is present. The reticulocyte count may also be elevated as a response to acute blood loss or for a short period after replacement therapy for iron, vitamin B₁₂, or folate deficiency. The marrow can increase its output 2-3–fold acutely, with a maximum of 6-8–fold in 3-fold.

Direct assessment of the severity of hemolysis requires measurement of RBC survival time using RBCs tagged with the radiotracer Na₂¹⁴CrO₄. The normal half-life of chromium 51–labeled RBCs is 25-35 days. This value is less than the expected half-life of 55-60 days because of the elution of chromium 51 from the labeled RBCs at the rate of approximately 1% day. Techniques to measure RBC survival using RBCs do not require the use of isotopes.

The exaggerated degradation rate of hemoglobin results in increased biliary excretion of heme pigments and increased urinary and fecal urobilinogen (Fig. 457-2). Gallstones composed of calcium bilirubinate may be formed in children with chronic hemolysis as young as 4 yr of age. Elevations of serum unconjugated bilirubin and lactate dehydrogenase also can accompany hemolysis.

Three heme-binding proteins in the plasma are altered during hemolysis (see Fig. 457-2). Hemoglobin binds to haptoglobin and hemopexin, both of which are cleared more rapidly as conjugates, resulting in a reduced plasma concentration. Oxidized heme binds to albumin to form methemalbumin, which is increased in the plasma. When the capacity of these binding molecules is exceeded, free hemoglobin appears in the plasma, and the pink color can be seen if the plasma is partitioned after centrifugation in a capillary hematocrit tube. If present, free hemoglobin in the plasma is prima facie evidence of intravascular hemolysis. Free hemoglobin dissociates into dimers and is filtered by the kidneys. When the tubular reabsorptive capacity of the kidneys for hemoglobin is exceeded, free hemoglobin appears in the urine. Even in the absence of hemoglobinuria, iron loss can result from reabsorbed hemoglobin and the shedding of renal epithelial cells in which the iron from hemoglobin is stored as hemosiderin. This iron loss can lead to iron deficiency during chronic intravascular hemolysis. When hemoglobin is degraded, an α-methylene bridge is broken in the cyclic tetrapyrrole of the heme moiety, with

As anemia becomes more severe, the erythropoietin concentration increases and reticulocytes are released from the marrow earlier; they are identifiable as reticulocytes in the blood that last for >1 day. Because the reticulocyte index is essentially a measure of RBC production per day, the maturation factor, μ, provides this correction (see Fig. 457-1).

The erythroid hyperplasia resulting from chronic hemolytic anemia in children, especially thalassemia, may be so extensive that the medullary spaces expand at the expense of the cortical bone. These changes may be evident on physical examination or on radiographs of the skull and long bones (see Fig. 462-7). A propensity to fracture long bones can also occur.

Figure 457-1 Number of days for maturation of reticulocytes to mature erythrocytes in the marrow and blood. The duration of maturation as blood reticulocytes is taken as μ, which is used in the correction equation in this chapter. (Modified from Hillman RS, Finch CA: Red cell manual, Philadelphia, 1983, FA Davis.)

Figure 457-2 Red cell destruction and catabolism of hemoglobin (Hb) based on the description by Hillman and Finch. Fe, iron. (From Hillman RS, Finch CA: Red cell manual, Philadelphia, 1983, FA Davis.)

Reticulocyte index = reticulocyte% × \( \frac{\text{Observed hematocrit}}{\text{Normal hematocrit}} \) × \( \frac{1}{\mu} \)

where μ is a maturation factor of 1-3 related to the severity of the anemia (Fig. 457-1). The normal reticulocyte index is 1.0; therefore, the index measures the fold increase in erythropoiesis (e.g., 2-fold, 3-fold).
release of carbon monoxide (CO) (see Fig. 457-2). The amount of CO in the blood or expired air provides a dynamic measure of the hemolytic rate; end-tidal CO is not available in most clinical laboratories to measure hemolysis.

The hematocrit level depends on the severity of hemolysis and on the erythropoietic response. The shortened RBC life span and heightened RBC production result in a marked susceptibility to aplastic or hypoplastic crises, characterized by erythroid marrow failure and reticulocytopenia, accompanied by a rapid reduction in hemoglobin and hematocrit to extremely low levels. The most common cause of aplastic crisis is infection with parvovirus B19, which is erythrocytropic (see Chapters 251 and 450). An aplastic crisis can produce a precipitous and life-threatening decline in hematocrit that usually lasts 10-14 days. Such transient erythroid marrow failure has only a mild effect in persons with a normal RBC life span, but it has a proportionately greater effect if the RBC life span is shortened by hemolysis. A second infection with parvovirus B19 is uncommon, but other infections can compromise erythroid marrow output, resulting in various degrees of hypoplasia or hypoplastic crises.

Hemolytic anemias may be classified as either cellular, resulting from intrinsic abnormalities of the membrane, enzymes, or hemoglobin; or extracellular, resulting from antibodies, mechanical factors, or plasma factors. Most cellular defects are inherited (paroxysmal nocturnal hemoglobinuria is acquired), and most extracellular defects are acquired (abetalipoproteinemia with acanthocytosis is inherited). Table 457-1 shows the most common hemolytic anemias, their underlying defects, the diagnostic laboratory tests, and recommendations for treatment.

*aHUS, atypical hemolytic uremic syndrome; Cu, copper; DIC, disseminated intravascular coagulation; ECMO, extracorporeal membrane oxygenation; G6PD, glucose-6-phosphate dehydrogenase; Hb, hemoglobin; HUS, hemolytic uremic syndrome; Ig, immunoglobulin; IVIG, intravenous immunoglobulin; LDL, low-density lipoprotein; K_m, Michaelis constant; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura; VLDL, very-low-density lipoprotein; V_max, maximal velocity; WBC, white blood cell.

Hereditary spherocytosis (HS) is a common cause of hemolysis and hemolytic anemia, with a prevalence of approximately 1 in 5,000 persons. It is the most common inherited abnormality of the red blood cell (RBC) membrane. Although common among persons of Northern European origin, HS has been described in most ethnic groups. The more rare defects found in the United States and in Europe are the more common mutations described in the Japanese population. The clinical spectrum varies widely. Affected patients may be asymptomatic, without anemia and with minimal hemolysis, or they may have severe hemolytic anemia requiring regular blood transfusions and a splenectomy.

ETIOLOGY
Hereditary spherocytosis usually is transmitted as an autosomal dominant or, less commonly, as an autosomal recessive disorder. As many as 25% of patients have no previous family history. Of these patients, most represent new mutations, and a few cases result from recessive inheritance or represent nonpaternity. The pathophysiology underlying HS involves 5 proteins, which are key components of the cytoskeleton responsible for RBC shape (Table 458-1). Abnormalities of spectrin or ankyrin are the most common molecular defects. Dominant defects have been described in β-spectrin and band 3. Recessive defects have been described in α-spectrin and protein 4.2. Both dominant and recessive defects have been described in ankyrin (Table 458-1). A deficiency in spectrin, band 3, ankyrin, or protein 4.2 results in uncoupling in the “vertical” interactions of the lipid bilayer skeleton and subsequent release of membrane microvesicles. The loss of membrane surface area without a proportional loss of cell volume causes sphering of the RBCs, and an associated increase in cation permeability and protein 4.1 in the RBC membrane (see Fig. 458-1). The need for exchange transfusion at birth or transfusions in infancy is not indicative of more severe disease later in life because infants do not mount an adequate reticulocyte response until several months after birth.

Some patients remain asymptomatic into adulthood, but others have severe anemia with pallor, jaundice, fatigue, and exercise intolerance. Severe cases may be marked by expansion of the diploë of the skull as a result of marrow hyperplasia (frontal bossing), but to a lesser extent than in thalassemia major. Depending on the severity of the anemia and the comorbidities associated with severe anemia, some patients benefit from a splenectomy (Table 458-2).

After infancy, splenomegaly is common; there is no correlation between spleen size and disease severity. Bilirubin gallstone formation is a function of age; they can form as early as age 4-5 yr and are present in the majority of adult patients.

Children with HS are also susceptible to aplastic crises, primarily as a result of parvovirus B19 infection, and to hypoplastic crises associated with various other infections (Fig. 458-3). High RBC turnover in the setting of erythroid marrow failure can result in profound anemia (hematocrit <10%), high-output heart failure, cardiovascular collapse, and death. White blood cell and platelet counts can also fall (Fig. 458-3). Rare complications associated with HS include splenic sequestration crisis, gout, cardiomyopathy, priapism, leg ulcers, and spinocerebellar degeneration.

DIAGNOSIS
Evidence of hemolysis includes reticulocytosis and indirect hyperbilirubinemia. The hemoglobin level usually is 6-10 g/dL, but it can be in the normal range. The reticulocyte percentage often is increased to 6-20%, with a mean of approximately 10%. The mean corpuscular

Part XXI  Diseases of the Blood

2332

Differential Diagnosis

The major alternative considerations when large numbers of spherocytes are seen on the blood smear are isoimmune and autoimmune hemolysis. Isoimmune hemolytic disease of the newborn, particularly when a result of ABO incompatibility, mimics the cell appearance of HS. The detection of antibody on an infant's RBCs using a direct antiglobulin (Coombs) test should establish the diagnosis of immune hemolysis. Autoimmune hemolytic anemias also are characterized by spherocytes; however, there may be evidence of previously normal values for hemoglobin, hematocrit, and reticulocyte count. Rare causes of spherocytosis include thermal injury, clostridial septicemia, and Wilson disease, each of which can manifest as transient hemolytic anemia (see Table 457-1 in Chapter 457).

Treatment

General Supportive Care

Parents should be advised of the risk of newborn jaundice and the potential need for phototherapy and exchange transfusion after birth to decrease bilirubin levels. Infants born to parents with known HS should be monitored carefully as hyperbilirubinemia may peak several days after birth. A minority of infants will be transfusion-dependent.
until development of adequate erythropoiesis to compensate for the ongoing hemolysis. Continued transfusion-dependence is not common after 6-12 mo of age.

Once the baseline level of disease severity is reached, an annual visit to the hematologist usually is sufficient. Growth should be monitored, exercise tolerance and spleen size documented, and parents should receive anticipatory guidance regarding the risk of aplastic crisis secondary to parvovirus, and hypoplastic crises with other infections. Parents and patients should be informed of an increased risk for gallstone development. The degree of splenomegaly does not correlate with disease severity. Folic acid supplementation is recommended in moderate and severe HS because of an enhanced requirement with increased erythropoiesis.

**Guidelines for Splenectomy**

Because the spherocytes are destroyed almost exclusively in the spleen, splenectomy eliminates most of the hemolysis. After splenectomy, the anemia, hyperbilirubinemia, and incidence of gallstones are significantly lessened, if not completely eradicated. However, splenectomy is associated with immediate surgical morbidities in addition to a lifelong increased risk for sepsis, particularly that caused by pneumococcal species. This risk is not completely eliminated with the requisite preoperative and postoperative vaccination against pneumococcus, meningococcus, and *Haemophilus influenzae type b*.

Splenectomy is recommended for patients with severe HS. It should be considered for patients with moderate HS and frequent hypoplastic or aplastic crises, poor growth, or cardiomegaly. It is generally not recommended for patients with mild HS. When splenectomy is indicated, it should be performed after the age of 6 yr, if possible, to avoid the heightened risk of postsplenectomy sepsis in younger children. The laparoscopic approach has less surgical morbidity and is recommended if the surgeon is adequately trained in this approach. Partial splenectomy may be beneficial but needs further study. In children undergoing splenectomy, a concomitant cholecystectomy should be performed if there are gallstones. It is controversial whether to perform a concomitant splenectomy in less-severely ill patients who are undergoing cholecystectomy for gallstone disease. Postsplenectomy thrombocytosis is commonly observed, but requires no treatment and usually resolves spontaneously. Vaccines for encapsulated organisms, such as pneumococcus, meningococcus, and *H. influenzae type b*, should be administered at least 14 days before splenectomy, and prophylactic oral penicillin VK prescribed indefinitely.

**Bibliography**

Hereditary elliptocytosis is a less common disorder than spherocytosis and also varies markedly in severity. Mild hereditary elliptocytosis produces no symptoms; more severe varieties can result in neonatal poikilocytosis (shape variation) and hemolysis, chronic or sporadic hemolytic anemia, or hereditary pyropoikilocytosis (HPP), which is a severe disorder with microspherocytosis and poikilocytosis. Hereditary elliptocytosis is rare in Western populations and is more common among West Africans.

ETIOLOGY
Hereditary elliptocytosis is inherited as a dominant disorder. In the rare instances, when 2 abnormal alleles are inherited (HPP), the patient exhibits particularly severe hemolytic anemia. Various molecular defects have been described in hereditary elliptocytosis; these produce abnormalities of α- and β-spectrin and defective spectrin heterodimer self-association (see Fig. 458-1). The abnormalities (spectrin mutations) can provide resistance to malarial infection. Such defects in horizontal protein interactions result in gross membrane fragmentation, particularly in homozygous HPP. Less commonly, mutations in protein 4.1 and glycoporphin C can produce elliptocytosis.

CLINICAL MANIFESTATIONS
Elliptocytosis may be an incidental finding on a blood film examination and might not be associated with clinically significant hemolysis (see Fig. 458-4B). The diagnosis of hereditary elliptocytosis is established by the findings on the blood film, the autosomal dominant inheritance pattern, and the absence of other causes of elliptocytosis, such as deficiencies of iron, folic acid, or vitamin B₁₂. Hemolytic elliptocytosis can produce neonatal jaundice, even though characteristic elliptocytosis might not be evident at that time. The blood of the affected newborn can show bizarre poikilocytes and pyknocytes. Transient augmented fragmentation and hemolysis in the newborn can result from the presence of hemoglobin F that binds poorly to the glycolytic intermediate 2,3-diphosphoglycerate. The increased 2,3-diphosphoglycerate tends to destabilize the spectrin–actin–protein 4.1 complex, leading to membrane instability (see Fig. 458-1).

The usual features of a chronic hemolytic process with elliptocytosis are manifested later as anemia, jaundice, splenomegaly, and osseous changes. Cholelithiasis can occur in later childhood; aplastic crises have been reported. The most severe form is HPP, which is characterized by extreme microcytosis (mean corpuscular volume, 50-60 fL/cell), extraordinary variation in cell size and shape, and primarily microspherocytic rather than elliptocytic cells (see Fig. 458-4C). The red blood cells (RBCs) have heightened sensitivity to heat, hence the “pyro” designation. These patients usually inherit a mutant spectrin from one parent, who has mild or no elliptocytosis (silent carrier), and a partial spectrin deficiency from the other parent, who is hematologically normal.

Ovalocytes, in contrast to elliptocytes, are less elongated and might reflect a condition known as Southeast Asian ovalocytosis (SAO). SAO is associated with an abnormal protein 3, which functions as an anion exchanger. This disorder can produce neonatal hyperbilirubinemia, but it causes little hemolysis later. It might offer protection against Plasmodium falciparum malaria because normal protein 3 is one of the malarial receptors. Protein 3 as an anion exchanger may be useful in conjunction with the mean corpuscular volume in diagnosing hereditary elliptocytosis and hereditary spherocytosis. Molecular defects are defined only in research laboratories.

LABORATORY FINDINGS
The blood film is the most important test to establish hereditary elliptocytosis (see Fig. 458-4B). The RBCs show various degrees of elongation and can actually be rod shaped. In hereditary elliptocytosis, other abnormal RBC shapes may be present, depending on the severity of hemolysis. They include microcytes, spherocytes, and other poikilocytes. The increase in the reticulocyte percentage reflects the severity of hemolysis; erythroid hyperplasia and indirect hyperbilirubinemia may be present. Increased thermal instability is characteristic of HPP. The abnormal spectrin denatures and the cells lyse at 45-46°C (113-114.8°F) instead of the usual 49-50°C (120.2-122°F). The specific protein abnormality can be established by protein separation and analysis techniques. The eosin-5-maleimide binding test, which detects binding to protein band 3 by flow cytometry, may be useful in conjunction with the mean corpuscular volume in diagnosing hereditary elliptocytosis and hereditary spherocytosis. Molecular defects are defined only in research laboratories.

TREATMENT
If hereditary elliptocytosis represents a morphologic abnormality on the blood film without evident hemolysis, no treatment is necessary. Patients with chronic hemolysis should receive folic acid. 1 mg daily, to prevent secondary folic acid deficiency. Splenectomy decreases the
hemolysis and should be considered if the hemoglobin is <10 g/dL and the reticulocyte count is >10%. The RBCs on the blood film may be more abnormal after splenectomy, even though hemoglobin increases and reticulocytes decrease. The hematologic features of SAO do not require treatment beyond the newborn period.

Bibliography
Hereditary stomatocytosis includes a rare group of dominantly inherited hemolytic anemias in which there are characteristic morphologic changes in the red blood cells (RBCs) and increased red cell cation permeability. The RBCs are cup-shaped, creating a mouth-shaped area (stoma) of central pallor instead of the usual circular area of central pallor. Hereditary stomatocytosis is classified by the RBC hydration status. The 2 major varieties are either overhydrated (hydrocytosis) or dehydrated (xerocytosis).

**HYDROCYTOSIS**

Pathophysiology

Stomatocytes of the hydrocytic variant have excess intracellular sodium and water content and decreased intracellular potassium content. The principal defect in this variant is an increase in Na\(^+\) and K\(^+\) permeability, caused by mutations in rhesus-associated glycoproteins. However, the amount of Na\(^+\) influx exceeds the K\(^+\) efflux, and the cells subsequently develop increased cation content and water, and thus swell. These hydrocytic cells have increased osmotic fragility. Additionally, the integral membrane protein, stomatin or band 7.2 b, is decreased or absent from the erythrocyte membrane. The function of stomatin is not fully understood, although it might act as a switch that influences the function of GLUT1, the glucose transporter. It has been found that stomatin in the hydrocytic variant is synthesized early in RBC development but is lost as the cell matures. The mechanism for this loss of stomatin is not yet determined. It also is unclear how the loss of stomatin expression contributes to the cation leak, which is characteristic of this variant.

**Clinical Features**

The hydrocytic variant is the most severe form of hereditary stomatocytosis and is characterized by moderate to severe hemolysis, macrocytosis, and large numbers of stomatocytes on the blood smear. Patients commonly develop jaundice, splenomegaly, and cholelithiasis.

**XEROCYTOSIS**

Pathophysiology

The xerocytic variant is the more common form of hereditary stomatocytosis and usually results in a milder anemia in affected patients. The underlying cation defect is a net loss of RBC potassium that is not accompanied by an increase in sodium. Subsequently, the erythrocyte develops decreased intracellular water content and becomes dehydrated. It may be associated with a syndrome of perinatal edema and ascites. These findings are transient and remain unexplained.

**Clinical Features**

Patients affected by the xerocytic variant have a mild compensated macrocytic hemolytic anemia, variable numbers of stomatocytes and/or target cells on peripheral smear, increased mean corpuscular hemo-

**INTERMEDIATE SYNDROMES**

The Rh deficiency syndrome is characterized by an absence or profound decrease in the Rh antigen on the RBC membrane. Affected RBCs in this disorder are dehydrated and have decreased cell cation and water content. This decreased cell cation content may be the result of increased potassium leak in spite of increased Na\(^+\)-K\(^+\) pump activity. This syndrome is associated with mild to moderate hemolytic anemia, reticulocytosis, and stomatocytes and spherocytes on the blood smear.

Cryohydrocytosis is a mild form of stomatocytosis, typically caused by mutations in SLC4A1 coding for the band 3 anion exchanger, in which the RBCs lyse on cooling in vitro and may be associated with “pseudohyperkalemia.”

Absence of high-density lipoproteins (an \(\alpha\)-lipoproteinemia or Tangier disease) can lead to hematologic manifestations such as a moderate hemolytic anemia, stomatocytosis, and thrombocytopenia. Affected patients can also have large orange tonsils, hepatosplenomegaly, lymphadenopathy, cloudy corneas, and peripheral neuropathy.

One of the most flagrant forms of stomatocytosis is seen in phytosterolemia, another metabolic disorder, in which the absorption of sterols, both cholesterol and its plant-derived relatives (e.g., sitosterol), is unlimited and unselective. The cells are not leaky to cations; there is macrothrombocytopenia and a degree of short stature. The plasma cholesterol may or may not be abnormal, but mass spectrography always shows a massive increase in plant sterol levels.

**OTHER DISORDERS ASSOCIATED WITH STOMATOCYTOSIS**

Acquired stomatocytosis may be seen with liver disease but also in alcoholism, malignancy, and cardiovascular disease. Stomatocytes can be seen on the blood smears of normal patients as a result of drying artifact.

**TREATMENT**

For severe hemolysis, patients might require RBC transfusion. Splenectomy is not recommended as a treatment for cation-leaky hereditary stomatocytosis. It is not effective and predisposes patients to in situ thrombosis after splenectomy. The thrombosis appears related to abnormal adherence of stomatocytic erythrocytes to the vascular endothelium.

Paroxysmal Nocturnal Hemoglobinuria and Acanthocytosis

George B. Segel

**Etiology**

Paroxysmal nocturnal hemoglobinuria (PNH) reflects an abnormality of marrow stem cells that affects each blood cell lineage. The disease is...
Paroxysmal Nocturnal Hemoglobinuria and Acanthocytosis

Chapter 461

an acquired somatic mutation that results in a defect in proteins of the cell membrane that renders the red blood cells (RBCs) and other cells susceptible to damage by normal plasma complement proteins (Fig. 461-1). The deficient membrane-associated proteins include decay-accelerating factor (CD55), the membrane inhibitor of reactive lysis (CD59), the C8 binding protein, and other proteins that normally impede complement lysis at various steps, specifically, the alternative pathway, which is constitutively activated. The underlying defect involves the glycolipid anchor that maintains these protective proteins on the cell surface. Various mutations in the PIGA gene that is involved in glycosylphosphatidylinositol anchor protein biosynthesis have been identified in patients with PNH. Glycosylphosphatidylinositol-deficient cells are found at low frequency in normal persons, suggesting that injury to the normal marrow stem cells provides a selective advantage to the progeny of PNH clones in the genesis of this disease.

Clinical Manifestations

PNH is a rare disorder in children. Approximately 60% of pediatric patients have marrow failure, and the remainder have either intermittent or chronic anemia, often with prominent intravascular hemolysis. Nocturnal and morning hemoglobinuria is a classic finding in adults when hemolysis is worse during sleep; chronic hemolysis is more common. In addition to chronic hemolysis, thrombocytopenia and hemoglobinuria are often characteristic. Hemoglobinuria is rarely seen in children compared to adults with PNH. Thrombosis and thromboembolic phenomena are serious complications that may be related to altered glycoproteins on the platelet surface and resultant platelet activation and production of procoagulant microparticles. Abdominal venous thrombosis presents as recurrent episodes of abdominal pain, Budd-Chiari syndrome (hepatic veins), or splenomegaly (splenic vein). Furthermore, released free hemoglobin results in depletion of nitric oxide, fostering vasconstriction, thrombosis, and pain. Back and head pain may also be prominent. Hypoplastic or aplastic pancytopenia can precede or follow the diagnosis of PNH; rarely, PNH may progress to acute myelogenous leukemia. At the time of presentation, more than 90% of patients with PNH have some blood abnormality (including ~35% with anemia alone, ~15% with anemia and thrombocytopenia, ~7% with anemia and neutropenia, and ~30% with pancytopenia), >10% have abdominal pain, and >5% have thrombosis. The mortality in PNH is related primarily to the development of aplastic anemia or thrombotic complications. The predicted survival rate for children before the development of eculizumab (see Treatment below) was 80% at 5 yr, 60% at 10 yr, and 28% at 20 yr.

Laboratory Findings

Hemosiderinuria, an elevated reticulocyte percentage, a low serum haptoglobin, and increased lactic dehydrogenase are common and reflect chronic intravascular hemolysis. Initially, the anemia is normocytic, but if iron deficiency develops, it becomes microcytic. Markedly reduced levels of RBC acetylcholinesterase activity and decay-accelerating factor also are found. Flow cytometry is the diagnostic test of choice for PNH. With the use of anti-CD59 for RBCs and anti-CD55 and anti-CD59 for granulocytes, flow cytometry is more sensitive than the classic RBC lysis (ham or sucrose) tests in detecting these reduced glycolipid-bound membrane proteins. Fluorescent-labeled aerolysin testing can heighten the sensitivity of detection by binding selectively to glycosylphosphatidylinositol anchors.

Treatment

Glucocorticoids such as prednisone (2 mg/kg/24 hr) have been used to treat acute hemolytic episodes; the dosage should be tapered as soon as the hemolysis abates. Prolonged anticoagulation (heparin or low-molecular-weight heparin) therapy may be of benefit when thromboses occur. Because of chronic urinary loss of iron as hemosiderin, iron therapy may be necessary. Androgens (e.g., fluoxymesterone [Halostatin]), antithymocyte globulin, cyclosporine, and growth factors (e.g., erythropoietin and granulocyte colony-stimulating factor) have been used to treat marrow failure. Bone marrow transplantation is successful in treating some cases; nonmyeloablative transplantation can reduce transplant-related mortality and morbidity.

PNH is also associated with 4 genetically diverse conditions (Table 461-1). These include chorea-akanthocytosis and the rare X-linked McLeod syndrome, which has absence of the KX (Kell) antigen, late-onset myopathy, peripheral neuropathy, chorea, splenomegaly, and hemolysis with acothocytosis. There is usually >3% acothocytosis on peripheral smear and caudate atrophy noted on MRI. Acothocytosis

also are seen in pantothenate kinase–associated neurodegeneration (dystonia, rigidity, chorea, dysarthria, spasticity, retinopathy) and Huntington disease–like 2. The production of acanthocytes in chorea-acanthocytosis appears related to altered Lyn kinase activity with increased tyrosine phosphorylation and altered linkage of band 3 to other RBC membrane proteins.

In contrast, echinocytes or “burr cells” have a more regular distribution of projections or serrations along the surface of the RBCs. They often are seen as artifact, and less often in end-stage renal disease, and in some patients with liver disease.

*Bibliography is available at Expert Consult.*
Bibliography
Great strides have been made in the management of both acute and chronic complications of sickle cell disease with a significant improvement in the life expectancy of a child born today in the United States. However, the majority of children with sickle cell disease are born outside of the United States with limited access to preventive care and disease-modifying treatments.

Children with sickle cell disease should be followed by experts in the management of this disease, most often by pediatric hematologists. Medical care provided by a pediatric hematologist is also associated with a decreased frequency of emergency department visits and length of hospitalization when compared to patients who were not seen by a hematologist within the last year.

PATHOPHYSIOLOGY
Hemoglobin S (HbS) is the result of a single base-pair change, thymine for adenine, at the sixth codon of the \( \beta \)-globin gene. This change encodes valine instead of glutamine in the 6th position in the \( \beta \)-globin molecule. Sickle cell anemia (HbSS), homozygous HbSS, occurs when both \( \beta \)-globin alleles have the sickle cell mutation (\( \beta \)s). Sickle cell disease refers to not only patients with sickle cell anemia, but also to compound heterozygotes where one \( \beta \)-globin allele includes the sickle cell mutation and the second \( \beta \)-globin allele includes a gene mutation other than the sickle cell mutation, such as HbC, \( \beta \)-thalassemia, HbD, and HbO\textsuperscript{A}kt. In sickle cell anemia, HbS is commonly as high as 90% of the total hemoglobin; whereas as in sickle cell disease, HbS is \( \geq 50\% \) of all hemoglobin.

In red blood cells, the hemoglobin molecule has a highly-specified conformation allowing for the transport of oxygen in the body. In the absence of globin-chain mutations, hemoglobin molecules do not interact with one another. However, the presence of HbS results in a conformational change in the hemoglobin tetramer and, in the deoxygenated state, HbS molecules can now interact with each other forming rigid polymers that give the red blood cell its characteristic “sickled” shape. The lung is the only organ capable of reversing the polymers, and any disease of the lung can be expected to compromise the degree of reversibility.

Intravascular sickling primarily occurs in the postcapillary venules and is a function of both mechanical obstruction by sickled red blood cells and increased adhesion between red blood cells, leukocytes and the vascular endothelium. Sickle cell disease is also an inflammatory disease based on nonspecific markers of inflammation, including, but not limited to, elevated baseline white blood cell count and cytokines.

DIAGNOSIS AND EPIDEMIOLOGY
Every state in the United States has instituted a mandatory newborn screening program for sickle cell disease. Such programs identify newborns with the disease and provide prompt diagnosis and referral to providers with expertise in sickle cell disease for anticipatory guidance and the initiation of penicillin before 4 mo of age.

The most commonly used procedures for newborn diagnosis include thin layer/isolectric focusing and high-performance liquid chromatography (HPLC). A confirmatory step is recommended, with all patients who have initial abnormal screens being retested during the first clinical visit and after 6 mo of age to determine the final hemoglobin phenotype. In addition, a complete blood count (CBC) and hemoglobin phenotype determination is recommended for both parents to confirm the diagnosis and to provide an opportunity for genetic counseling. Table 462-1 correlates the initial hemoglobin phenotype at birth with the type of hemoglobinopathy; baseline hemoglobin range, and requirement for a hematologist.

In newborn screening programs, the hemoglobin with the greatest quantity is reported first, followed by other hemoglobins in order of decreasing quantity. In newborns with a hemoglobin analysis result...
of FS, the pattern supports HbSS, Hbs hereditary persistent fetal hemoglobin (HPFH), or HbSB-thalassemia zero. In a newborn with a hemoglobin analysis of FSA, the pattern is supportive of diagnosis HbSB-thalassemiα+ The diagnosis of HbSB-thalassemia+ is confirmed if at least 50% of the hemoglobin is Hbs, HbA is present, and the amount of HbA2 is elevated (typically >3.5%); although, HbA2 is not elevated in the newborn period. In newborns with a hemoglobin analysis of FSC, the pattern supports a diagnosis of HbSC. In newborns with a hemoglobin analysis of FAS, the pattern supports a diagnosis of HbAS (sickle cell trait).

A newborn with a hemoglobin analysis of AFS has been transfused with red blood cells prior to collection of the newborn screen because the amount of HbA is greater than the amount of HbF or there has been an error. The patient may have either sickle cell disease or sickle cell trait and should be started on penicillin prophylaxis until the final diagnosis can be determined.

Given the implications of a diagnosis of sickle cell disease versus sickle cell trait in a newborn, repeating the hemoglobin analysis in the parents for genetic counseling cannot be overemphasized. Unintended mistakes do occur in state newborn screening programs. Newborns who have the initial phenotype of HbFBS but whose final true phenotype included HbSB-thalassemia+ whose possible hemoglobin trait result back separately to each parent during separate visits.

The United States sickle cell disease is the most common genetic disorder identified through the state-mandated newborn screening program, occurring in 1:2,647. In regard to race in the United States, sickle cell disease occurs in African-Americans at a rate of 1:396 births, and in Hispanics at a rate of 1:36,000 births. In the United States, an estimated 90,000 people are affected by sickle cell disease, with an ethnic distribution of 90% African-American and 10% Hispanic. The United States sickle cell disease population represents a fraction of the worldwide burden of the disease, with global estimates of 312,000 neonates born annually with HbSS disease.

‡Impossible to determine the diagnosis because the infant received a blood transfusion before testing.

#### CLINICAL MANIFESTATIONS AND TREATMENT OF SICKLE CELL ANEMIA (Hb SS)

**Fever and Bacteremia**

**Fever** in a child with sickle cell anemia is a medical emergency, requiring prompt medical evaluation and delivery of antibiotics because of the increased risk of bacterial infection and subsequent high mortality rate. Infants with sickle cell anemia, as early as 6 mo of age, develop abnormal immune function due to splenic infarction. By 5 yr of age, most children with sickle cell anemia have complete functional asplenia. Regardless of age, all patients with sickle cell anemia are at increased risk of infection and death from bacterial infection, particularly encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, and *Neisseria meningitidis*.

The rate of bacteremia in children with sickle cell disease, presenting with fever in busy pediatric emergency department is less than 1%. Several clinical strategies have been developed to manage children with sickle cell anemia who present with fever. These vary from hospital admission for intravenous (IV) antimicrobial therapy to administering a 3rd-generation cephalosporin in an emergency department or outpatient setting to patients without established risk factors for occult bacteremia (Table 462-2). Given the observation that the average time for a positive blood culture is <20 hr in children with sickle cell anemia, admission for 24 hr is probably the most prudent strategy for children and families who live out of town or who are identified as high risk for poor follow-up.

Outpatient management of fever without a source should be considered in children with the lowest risk of bacteremia and after intravenous ceftriaxone or other cephalosporin is given. Observation after antibiotic administration is important as children who have sickle cell anemia treated with ceftriaxone can develop severe, rapid, and life-threatening immune hemolysis. In the event that *Salmonella* spp. or *Staphylococcus aureus* bacteremia occurs, strong consideration should be given to an evaluation for osteomyelitis with a bone scan given the increased risk of osteomyelitis in children with sickle cell anemia when compared to the general population.

**Aplastic Crisis**

Human parvovirus B19 poses a unique threat for patients with sickle cell anemia because such infections result in temporary red cell aplasia, limiting the production of reticulocytes and causing profound anemia. Any child with sickle cell disease, fever, and reticulocytopenia should be considered to have parvovirus B19 until proven otherwise. The acute anemia of an aplastic crisis is treated conservatively using...

red blood cell transfusion when the patient becomes hemodynamically symptomatic or has a concurrent illness, such as acute chest syndrome. In addition, acute infection with parvovirus B19 is associated with pain, splenic sequestration, acute chest syndrome (ACS), glomerulonephritis, and stroke. Patients with parvovirus-associated aplastic crisis are contagious and infection precautions should be taken to avoid nosocomial spread of the infection.

**Splenic Sequestration**

Acute splenic sequestration is a life-threatening complication occurring primarily in infants and young children with sickle cell anemia. The incidence of splenic sequestration has declined from an estimated 30% to 12.6% with early identification by newborn screening and parental education. Sequestration can occur as early as 5 wk of age, but most often occurs in children between the ages of 6 mo and 2 yr.

Splenic sequestration is associated with rapid spleen enlargement causing left-sided abdominal pain and a decline in hemoglobin of at least 2 g/dL from the patient's baseline. Sequestration may lead to signs of hypovolemia as a result of the trapping of blood in the spleen: profound anemia, with total hemoglobin falling below 3 g/dL, has been reported. Reticulocytosis and a decrease in the platelet count may also be present. Sequestration may be triggered by fever, bacteremia, or viral infections.

Treatment includes early intervention and maintenance of hemodynamic stability using isotonic fluid or blood transfusions. Careful blood transfusions with red blood cells are recommended to treat both the sequestration and the resultant anemia. Blood transfusion aborts the red blood cell sickling in the spleen and allows release of the patient's blood cells that have become sequestered, often raising the hemoglobin above baseline values. We typically recommend only 5 mL/kg of red blood cells because the goal is to prevent hypovolemia. Blood transfusion that results in hemoglobin levels above 10 g/dL may put the patient at risk for hyperviscosity syndrome because of the risk that that patient may release the blood within the spleen.

Repeated episodes of splenic sequestration are common, occurring in two-thirds of patients. Most recurrent episodes develop within 6 mo of the previous episode. Prophylactic splenectomy performed after an acute episode has resolved is the only effective strategy for preventing future life-threatening episodes. Although blood transfusion therapy has been used with the goal of preventing subsequent episodes, evidence strongly suggests this strategy does not reduce the risk of recurrent splenic sequestration when compared to no transfusion therapy.

Furthermore, prophylactic blood transfusion therapy may put the patient at risk for autotransfusion (the phenomenon when the blood sequestered in the spleen is released and dramatically increases the hemoglobin concentration, putting the patient at risk for hyperviscosity syndrome).

**Hepatic and Gallbladder Involvement**

See Chapters 360 and 366.

**Sickle Cell Pain**

Dactylitis, referred to as hand-foot syndrome, is often the first manifestation of pain in infants and young children with sickle cell anemia, occurring in 50% of children by their 2nd yr of life (Fig. 462-1). Dactylitis often manifests with symmetric or unilateral swelling of the hands and/or feet. Unilateral dactylitis can be confused with osteomyelitis, and careful evaluation to distinguish between the two is important because treatment differs significantly. Dactylitis requires palliation with pain medications, such as hydrocodone, whereas osteomyelitis requires at least 4-6 wk of IV antibiotics. Given the recent association between genotype and metabolism of codeine, a subgroup of children may not get pain relief from codeine. Hence, feedback from the parents is needed to determine if therapy was successful in relieving pain.

The cardinal clinical feature of sickle cell anemia is acute vasocclusive pain. No written definition can describe the visual picture of a child with sickle cell anemia experiencing pain. Acute sickle cell pain is characterized as unrelenting discomfort that can occur in any part of the body but most often occurs in the chest, abdomen, or extremities. These painful episodes are often abrupt and cause disruption of daily life activities and anguish for children and their caregivers. A patient with sickle cell anemia has approximately 1 painful episode per year that requires medical attention.

The exact etiology of pain is unknown, but the pathogenesis is initiated when blood flow is disrupted in the microvasculature by sickled cells, resulting in tissue ischemia. Acute sickle cell pain may be precipitated by physical stress, infection, dehydration, hypoxia, local or systemic acidosis, exposure to cold, and swimming for prolonged periods. Successful treatment of painful episodes requires education of both the caregivers and patients regarding the recognition of symptoms and the optimal management strategy. Given the absence of any
Summary of the Chronology of Pain in Children with Sickle Cell Disease

Pain intensity is at a tolerable level, and no vasoocclusive pain; pain of complications. First signs of vasoocclusive pain appear, with sickle cell anemia are managed at home with comfort measures, such as heating blanket, relaxation techniques, massage, and oral pain medication. Although pain scales have proved useful for some children, others require prenegotiated activities to determine when opioid therapy should be initiated and decreased. For instance, sleeping through the night might be an indication for decreasing pain medication by 20% the following morning. The majority of painful episodes in patients with sickle cell anemia are managed at home with comfort measures, such as heating blanket, relaxation techniques, massage, and oral pain medication.

</table>

Several myths have been propagated regarding the treatment of pain in sickle cell anemia. The concept that painful episodes in children should be managed without opioids is without foundation and results in unwarranted suffering on the part of the patient. Blood transfusion therapy during an existing painful episode does not decrease the intensity or duration of the painful episode as tissue necrosis occurs well before the ability to administer the transfusion. Intravenous hydration does not relieve or prevent pain and is appropriate when the patient is dehydrated or unable to drink as a result of the severe pain. Opioid dependency in children with sickle cell anemia is rare and should never be used as a reason to withhold pain medication. However, patients with multiple painful episodes requiring hospitalization within a year or with pain episodes that require hospitalization for more than 7 days should be evaluated for comorbidities and environmental stressors that are contributing to the frequency or duration of pain. Children with chronic pain should be evaluated for other reasons associated with vasoocclusive pain episodes, including, but not limited to, overexertion with physical activities, such as participating in the school band, sports, or heavy lifting of backpacks to and from school and up and down steps. A careful history is warranted to distinguish chronic pain that often is not relieved by opioids alone versus acute unremitting vasoocclusive pain episodes.

Skeletal pain (bone or bone marrow infarction) with or without fever must be differentiated from osteomyelitis. Both Salmonella spp. and S. aureus cause osteomyelitis in children with sickle cell anemia, which is often in the diaphysis of long bones (in contrast to children without sickle cell anemia where osteomyelitis is in the metaphyseal region of the bone). Differentiating osteonecrosis from a vasoocclusive...
creatitis and osteomyelitis is often difficult; patients with osteomyelitis often have a longer duration of fever and pain, swelling of the affected area, fewer or only 1 location of pain and tenderness, higher white blood cell counts, and an elevated C-reactive protein. Blood cultures, when positive, are helpful.

Imaging studies, which must include MRI with contrast, are helpful in distinguishing osteomyelitis from bone or marrow infarction, although rarely an osteomyelitis may initially appear “cold” (infarctive osteomyelitis), whereas an infarct, over time, may appear hyperemic as it heals. Both lesions may demonstrate marrow signal intensity abnormalities, periosteal elevation, and bone, periosteal, or extraosseous fluid collections. MRI findings suggestive of osteomyelitis include localized medullary fluid, sequestrum, and cortical defects. Ultimately, aspiration with or without biopsy and culture will be needed to differentiate the 2 processes (see Chapter 684).

**Avascular Necrosis**

Avascular necrosis (AVN) occurs at a higher rate among children with sickle cell anemia than in the general population, and is a source of both acute and chronic pain. Most commonly, the femoral head is affected and AVN. Unfortunately, the AVN of the hip may cause limp and leg-length discrepancy. Other sites affected include the humeral head and mandible. Risk factors for AVN include HbSS disease with α-thalassemia trait, frequent vasoocclusive episodes, and elevated hematocrit (for patients with sickle cell anemia). Optimal treatment of AVN has not been determined and individual management requires consultation with the disease-specific specialist, orthopedic surgeon, physical therapist, hematologist and primary care physician. Initial management may include referral to a physical therapist to address strategies to increase strength and decrease weight bearing daily activities that may exacerbate the pain associated with AVN. Opioids are often used, but usually can be tapered after the acute pain has subsided with AVN. Regular blood transfusion therapy has not been demonstrated as an effective therapy to abate the acute and chronic pain associated AVN.

**Priapism**

Priapism is defined as an unwanted painful erection of the penis and most commonly affects males with sickle cell anemia. The mean age of first episode is 15 yr, although priapism has been reported in children as young as 3 yr. The actuarial probability of a patient experiencing priapism is approximately 90% by 20 yr of age.

Priapism occurs in 2 patterns: prolonged, lasting more than 4 hr, or stuttering, with brief episodes that resolve spontaneously but may occur in clusters and herald a prolonged event. Both types occur from early childhood to adulthood. Most episodes occur between 3 a.m. and 9 a.m. Priapism in sickle cell disease represents a low flow state caused by venous stasis from sickling of red blood cells in the corpora cavernosa. Recurrent prolonged episodes of priapism are associated with impotence.

The optimal treatment for acute priapism is unknown. Acutely, supportive therapy, such as a hot shower, short aerobic exercise, or pain medication, is commonly used by patients at home. A prolonged episode lasting >4 hr should be treated by aspiration of blood from the corpora cavernosa followed by irrigation with dilute epinephrine to produce immediate and sustained detumescence. Urology consultation is required to initiate this procedure, with appropriate input from a hematologist. Simple blood transfusion and exchange transfusion has been proposed for the acute treatment of priapism, but limited evidence supports this strategy as the initial management. We typically refer a patient to the urology service first, and if no benefit is obtained from surgical management, consider transfusion therapy. However, detumescence may not occur for up to 24 hr (far longer than with urologic aspiration) after transfusion and transfusion for priapism has been associated with acute neurologic events.

**Neurologic Complications**

Neurologic complications associated with sickle cell anemia are varied and complex, ranging from acute ischemic stroke with focal neurologic deficit to clinically silent abnormalities found on radiologic imaging. Prior to the development of transcranial Doppler to screen for stroke risk among children with sickle cell anemia, approximately 11% experienced an overt stroke and 20% a silent stroke before their 18th birthday. A functional definition of overt stroke is the presence of a focal neurologic deficit lasting for >24 hr and/or abnormal neuro-imaging of the brain indicating a cerebral infarct on T2-weighted magnetic resonance imaging (MRI) corresponding to the focal neurologic deficit (Figs. 462-2 and 462-3). A silent cerebral infarct, as its name indicates, lacks focal neurologic findings lasting >24 hr and is diagnosed by abnormal imaging on T2-weighted MRI. Children with other

![Figure 462-2 T2-weighted MRI and magnetic resonance angiography of the brain. A, T2-weighted MRI shows remote infarction of the territories of the left anterior cerebral artery and middle cerebral artery. B, Magnetic resonance angiography shows occlusion of the left internal carotid artery siphon distal to the takeoff of the ophthalmic artery.](image-url)
types of sickle cell disease, such as HbSC or HbSβ-thalassemia+, develop overt or silent cerebral infarcts as well, but at a lower frequency than children with HbSS and HbSβ-thalassemia zero. Other neurologic complications include headaches that may or may not correlate to degree of anemia, seizures, cerebral venous thrombosis and reversible posterior leukoencephalopathy syndrome, also referred to as posterior reversible encephalopathy syndrome (PRES).

For patients presenting with acute focal neurologic deficit, a prompt pediatric neurologic evaluation is recommended, as well as consultation with a pediatric hematologist. In addition, oxygen administration to keep oxygen saturations >96% and simple blood transfusion within 1 hr of presentation with a goal of increasing the hemoglobin to a maximum of 10 g/dL is warranted. A timely simple blood transfusion is important because this is the most efficient strategy to dramatically increase oxygen content of the blood, if the oxygen saturation is above 96%. To exceed this hemoglobin threshold limits oxygen delivery to the brain as a result of hyperviscosity by increasing the hemoglobin significantly over the patient’s baseline values. Subsequently, prompt treatment with an exchange transfusion should be considered, either manually or with automated erythrocytapheresis, to reduce the HbS percentage to at least <50%, and ideally to <30%. Exchange transfusion at the time of acute stroke is associated with a decreased risk of second stroke when compared to simple transfusion alone. Computed tomography (CT) of the head to exclude cerebral hemorrhage should be performed as soon as possible, and if available, MRI of the brain with diffusion-weighted imaging to distinguish between ischemic infarcts and PRES. Magnetic resonance (MR) venography is useful to evaluate the possibility of cerebral venous thrombosis, a rare but potential cause of focal neurologic deficit in children with sickle cell disease. MR angiography may identify evidence of cerebral vasculopathy; these images are not critical in the initial time management of a child with sickle cell disease presenting with a focal neurologic deficit.

The clinical presentation of PRES or central venous thrombosis can mimic a stroke but would require a different treatment course. For both PRES and cerebral venous thrombosis, the optimal management has not been defined in patients with sickle cell disease, resulting in the need for consultation with both a pediatric neurologist and a pediatric hematologist.

Transcranial Doppler Ultrasonography

Primary prevention of overt stroke can be accomplished using transcranial Doppler ultrasonography (TCD) assessment of the blood velocity in the terminal portion of the internal carotid and the proximal portion of the middle cerebral artery. Children with sickle cell anemia with an elevated time-averaged mean maximum (TAMM) blood-flow velocity >200 cm/sec are at increased risk for a cerebrovascular event. A TAMM measurement of <200 cm/sec but ≥180 cm/sec represents a conditional threshold. A repeat measurement is suggested within a few months because of the high rate of conversion to a TCD velocity >200 cm/sec in this group of patients.

Two distinct methods of measuring TCD velocity exist: a nonimaging and an imaging technique. The nonimaging technique was the method used in the TCD trial sponsored by the National Institutes of Health, whereas most pediatric radiologists in practice use the imaging technique. When compared to each other, the imaging technique produces values that are 10-15% below that of the nonimaging technique. The imaging technique uses the time-averaged mean of the maximum velocity (TAMM), and this measure is believed to be equivalent to the nonimaging calculation of TAMM. A downward adjustment for the transfusion threshold is appropriate for centers using the imaging method to assess TCD velocity. The magnitude of the transfusion threshold in the imaging technique has not been settled, but a transfusion threshold of a TAMM of 185 cm/sec and a conditional threshold of TAMM of 165 cm/sec, seems reasonable.

The primary approach for prevention of recurrent overt stroke is blood transfusion therapy aimed at keeping the maximum HbS concentration <30%. Despite regular blood transfusion therapy, around 20% of patients will have a second stroke and 30% of this group will have a third stroke. Children with TCD values above defined thresholds should begin chronic blood transfusion therapy to maintain HbS levels <30% to decrease the risk of first stroke. This strategy results in an 85% reduction in the rate of overt strokes. Once transfusion therapy is initiated, patients are expected to continue it indefinitely as discontinuation of blood transfusion therapy is associated with an increase in the development of silent infarcts.

Pulmonary Complications

Lung disease in children with sickle cell anemia is the second most common reason for hospital admission and is associated with significant mortality. ACS refers to a life-threatening pulmonary complication of sickle cell disease defined as a new radiodensity on chest radiography plus any 2 of the following: fever, respiratory distress, hypoxia, cough, or chest pain (Fig. 462-4). Even in the absence of respiratory symptoms, all patients with fever should receive a chest radiograph to identify evolving ACS because clinical examination alone is insufficient to identify patients with a new radiographic density and early detection of ACS will alter clinical management. The radiographic findings in ACS are variable but may include single lobe involvement, predominantly left lower lobe; multiple lobes, most often both lower lobes; and pleural effusions, either unilateral or bilateral. ACS may progress rapidly from a simple infiltrate to extensive infiltrates and a pleural effusion. Therefore, continued pulse oximetry and frequent clinical exams are required, and repeat chest x-rays are indicated for progressive hypoxia, dyspnea, tachypnea, and other signs of respiratory distress.

The majority of patients with ACS do not have a single identifiable cause. Infection is the most well-known etiology, yet only 30% of ACS episodes will have positive sputum or bronchoalveolar culture, and the most common pathogens are S. pneumoniae, Mycoplasma pneumoniae, and Chlamydia sp. The most frequent event preceding ACS is a painful episode requiring systemic opioid treatment. Fat emboli has also been implicated as a cause of ACS, arising from infarcted bone marrow, and can be life-threatening if large amounts are released to the lungs. Fat

- Nasopharyngeal samples for viral culture (respiratory syncytial virus, influenza)
- Blood counts every day and appropriate chemistries
- Continuous pulse oximetry
- Chest radiographs

### LABORATORY MONITORING

- Blood counts every day and appropriate chemistries
- Continuous pulse oximetry
- Chest radiographs

### Pulmonary Hypertension

Pulmonary hypertension has been identified as a major risk factor for death in adults with sickle cell anemia. The natural history of pulmonary hypertension in children with sickle cell anemia is unknown. Optimal strategies for screening at risk patients have not been identified (echocardiogram results are not supported by right heart catheterization results demonstrating elevated pulmonary artery pressures) and the best diagnostic methodology carries significant risk of harm. Attempts to identify targeted therapeutic interventions to alter the natural history of pulmonary hypertension in adults have been unsuccessful.

### Renal Disease and Enuresis

Renal disease among patients with sickle cell disease is a major comorbid condition that can lead to premature death. Seven sickle cell disease nephropathies have been identified: (1) gross hematuria, (2) papillary necrosis, (3) nephrotic syndrome, (4) renal infarction, (5) hypothesnuria, (6) pyelonephritis, and (7) renal medullary carcinoma. As expected, the presentation of these entities is varied but may include...
hematuria, proteinuria, renal insufficiency, concentrating defects, or hypertension.

The common presence of nocturnal enuresis occurring in children with sickle cell anemia is not well defined but is troublesome to affected children and their parents. The overall prevalence of enuresis was 33% in the Cooperative Study of Sickle Cell Disease with the highest prevalence (42%) among children ages 6-8 yr. Furthermore, enuresis may still occur in approximately 9% of the older adolescent group. As would be the case in all children with nocturnal enuresis, we would systematically evaluate the children for recurrent urinary tract infections, kidney function, and possibly obstructive sleep apnea syndrome with a supportive history. Unfortunately, most children with nocturnal enuresis do not have an etiology and targeted therapeutic interventions have been of limited success.

Cognitive and Psychological Complications

As with any child with a chronic illness, good health maintenance must include routine psychological and social assessment. Ongoing evaluation of the family unit and identification of the resources available to cope with a chronic illness are critical for optimal management. Children and adolescents with sickle cell disease also have decreased quality of life, as measured on standardized assessments, compared to their siblings and children with other chronic diseases. Furthermore, children with sickle cell disease are at great risk for academic failure and have a 20% high school graduation rate. One reason behind the low high school graduation rate is that approximately a third of children with sickle cell anemia have had a cerebral infarct—either silent cerebral infarcts or overt strokes. Children with cerebral infarcts require ongoing cognitive and school performance assessment so that education resources can be focused to optimize educational attainment. Relevant support groups and attendance in group activities, such as camps for children with sickle cell disease, may be of direct benefit by improving self-esteem and establishing peer relationships.

Other Complications

In addition to the previously mentioned organ dysfunctions, patients with sickle cell anemia can have other significant complications. These complications include, but are not limited to sickle cell retinopathy, delayed onset of puberty, and leg ulcers. Optimal treatment for each of these entities has not been determined and individual management requires consultation with the disease-specific specialist, a hematologist, and primary care physician.

THERAPEUTIC CONSIDERATIONS

Hydroxyurea

Hydroxyurea, a myelosuppressive agent, is the only drug proven effective in reducing the frequency of painful episodes. In a large clinical trial of adults with sickle cell anemia, hydroxyurea was found to decrease the rate of hospitalization for painful episodes by 50% and the rate of ACS and blood transfusion by almost 50%. Follow-up of the original trial found that adults taking hydroxyurea had shorter hospital stays and required less pain medication during hospitalization. In children with sickle cell anemia, a safety feasibility trial of hydroxyurea demonstrated that hydroxyurea was safe and well tolerated in children >5 yr of age. No clinical adverse events were identified in this study; the primary toxicities were limited to myelosuppression that reversed upon cessation of the drug. Infants treated with hydroxyurea also experienced fewer episodes of pain, dactylitis, and ACS, and were less-often hospitalized or received a blood transfusion. Despite being a myelosuppressive agent, the infants treated with hydroxyurea did not experience increased rates of bacteremia or serious infection.

Hydroxyurea may be indicated for other sickle cell–related complications, especially in patients who are unable to tolerate other treatments. For patients who either will not or cannot continue blood transfusion therapy to prevent recurrent stroke, hydroxyurea therapy may be a reasonable alternative. The trial assessing the efficacy of hydroxyurea as an alternative to transfusions to prevent second stroke was terminated early after the data safety and monitoring found an increased stroke rate in the hydroxyurea arm compared to the transfusion arm (0 vs. 7 [10%]). Hydroxyurea alone is inferior to transfusion therapy for secondary stroke prevention in patients who do not have contraindications to ongoing transfusions. Although not investigated as a primary outcome, hydroxyurea appears to have promise for the prevention of recurrent priapism. One study found hydroxyurea decreased glomerular hyperfiltration in young children with sickle cell anemia.

The long-term toxicity associated with initiating hydroxyurea in very young children has not yet been established. However, all evidence to date suggests that the benefits far outweigh the risks. For these reasons, children ≥2 yr of age receiving hydroxyurea require well-informed parents and medical care by pediatric hematologists, or at least comanagement by a physician with expertise in immunosuppressive medications. The typical starting dose of hydroxyurea is 15-20 mg/kg given once daily, with an incremental dosage increase every 8 wk of 5 mg/kg, and if no toxicities occur, up to a maximum of 35 mg/kg per dose. The infant hydroxyurea study found young children could safely be started at 20 mg/kg/day without increased toxicity. Achievement of the therapeutic effect of hydroxyurea can require several months, and for this reason, inpatient initiating of hydroxyurea is not optimal. We prefer to introduce the concept to parents within the first year of life, provide literature that describes both the pros and cons of starting hydroxyurea in children with severe symptoms of sickle cell disease, and educate parents on starting hydroxyurea in asymptomatic children as a preventative therapy for repetitive pain and ACS events. Other effects of hydroxyurea that may vary include an increase in the total hemoglobin level and a decrease in the TCD velocity.

Hematopoietic Stem Cell Transplantation

The only cure for sickle cell anemia is transplantation with human leukocyte antigen (HLA)–matched hematopoietic stem cells from a sibling or unrelated donor. The most common indications for transplant are recurrent ACS, stroke and abnormal TCD. Sibling-matched stem cell transplantation has a lower risk for graft-versus-host disease than unrelated donors. However, few children have suitable sibling donors. Stem cell transplantation using an unrelated but well-matched donor is the subject of an open clinical trial. The decision to consider unrelated transplantation should involve appropriate consultation and counseling from physicians with expertise in sickle cell transplantation.

Stem cell transplantation for children with sickle cell disease with a genetically matched sibling is not routinely done, in part because of the known risk of transplantation-related mortality and morbidity in a short period of time, commonly less than 2 yr after the transplantation versus the high probability that patients will live to and through adulthood. The use of hydroxyurea has dramatically decreased the disease burden for the patient and family, with associated far fewer hospitalizations for pain or ACS episodes and less use of blood transfusions. Furthermore, the field of stem cell transplantation is progressing so rapidly that in a decade or less haplo-identical transplantation will be considered a viable option for not only individuals with severe disease, but also those with less-severe manifestations. Haplo-identical transplantations in adults with severe manifestations of sickle cell disease resulted in no deaths, and approximately 60% of the participants were cured of the disease. Low intensity, nonmyeloablative HLA-matched sibling allogenic stem cell transplantation has been employed in patients ≥16 years of age.

Red Blood Cell Transfusions

Red blood cell transfusions are frequently used in the management of children with sickle cell anemia, both in the treatment of acute complications such as ACS, aplastic crisis, splenic sequestration, and acute stroke, and to prevent surgery-related ACS and first stroke in patients with abnormal TCD or MRI findings (silent stroke). Patients with sickle cell disease are at increased risk of developing alloantibodies to less-common red cell surface antigens after receiving even a single transfusion. In addition to standard cross-matching for major blood group antigens (A, B, O, RhD), more extended matching should be performed to identify donor units that are C-, E-, and Kell-antigen
negative. Some centers have begun to perform full red blood cell phenotype for patients receiving chronic blood transfusions.

Three methods of blood transfusion therapy are used in the management of acute and chronic complications associated with sickle cell anemia: automated erythrocytapheresis, manual exchange transfusion (phlebotomy of a set amount of patient’s blood followed by rapid administration of donated packed red blood cells), and simple transfusion. Automated erythrocytapheresis is the preferred method for patients requiring chronic blood transfusion therapy because there is a minimum net iron balance after the procedure, followed by manual exchange transfusion. Simple transfusion therapy is the least-preferable method for regular blood transfusion therapy because this strategy results in the highest net-positive iron balance after the procedure. Despite being the preferred method, erythrocytapheresis is less-frequently performed because of the requirement of technical expertise, large venous access, multiple units of matched red blood cells, and an available cytopheresis machine.

Preparation for surgery for children with sickle cell disease requires a coordinated effort between the hematologist, surgeon, and primary care provider. ACS and pain are the 2 most common postoperative complications, with ACS being a significant risk factor for postoperative death. Blood transfusion prior to surgery for children with sickle cell anemia is recommended to raise the hemoglobin level preoperatively to no more than 10 g/dL, although benefit also may be seen at lower hemoglobin values. The rate of serious complications, including a higher rate of ACS in patients who do not receive blood transfusion when compared to those who do. When available, blood transfusion therapy prior to surgery should be the standard approach. When preparing a child with sickle cell anemia for surgery with a simple blood transfusion, caution must be used not to elevate the hemoglobin beyond 10 g/dL because of the risk of hyperviscosity syndrome. For children with sickle cell anemia, exchange transfusion prior to surgery is of no greater benefit than simple blood transfusion and carries significantly higher risk of red blood cell alloimmunization. For children with milder forms of sickle cell disease, such as HbSC or HbSβ-thalassemia, a decision must be made on a case-by-case basis as to whether an exchange transfusion is warranted, because a simple transfusion may raise the hemoglobin to an unacceptable level.

Excessive Iron Stores
The primary toxic effect of blood transfusion therapy relates to excessive iron stores, which can result in organ damage and premature death. Excessive iron stores develop after 100 mL/kg of red cell transfusion or about 10 transfusions. The assessment of iron overload in children receiving regular blood transfusions is difficult. The most commonly used and least-invasive method of estimating total-body iron involves serum ferritin levels. Ferritin measurements have significant limitations in their ability to estimate iron stores for several reasons, including, but not limited to, elevation during acute inflammation and poor correlation with excessive iron in specific organs after 2 yr of regular blood transfusion therapy. Advances in technology have improved the assessment of iron stores among children with sickle cell disease receiving regular blood transfusion therapy. MRI of the liver has proven to be the most effective and common approach for assessment of iron stores. The imaging strategy is more accurate than serum ferritin in measuring heart and liver iron content. MRI T2* and MRI R2 and R2* sequences are now being used to estimate iron levels in the heart and liver. The standard for iron assessment previously was biopsy of the liver, which is an invasive procedure exposing children to the risk of general anesthesia, bleeding, and pain. Liver biopsy alone does not accurately estimate total-body iron, as iron deposition in the liver is not homogenous and varies among the affected organs; that is, the amount of iron found in the liver is not equivalent to cardiac tissues. The major advantage of a liver biopsy is that histologic assessment of the parenchyma can be ascertained along with appropriate staging of suspected pathology, particularly cirrhosis.

The primary treatment of excessive iron stores resulting from red blood cell transfusion requires iron chelation using medical therapy. In the United States, 3 chelating agents are commercially available and approved for use in transfusional iron overload. Deferoxamine is administered subcutaneously 5 of 7 nights/wk for 10 hr a night. Deferasirox is an effervescent tablet that is dissolved in liquid and taken by mouth daily, and deferasirox is available in tablets taken orally twice a day. The FDA approved deferasirox, the newest orally administered chelator, in 2005 for use in patients age ≥2 yr. Deferiprone is an older oral chelator that has been widely used outside of the United States for many years and was approved by the FDA in 2011, but requires weekly monitoring of complete blood counts because of a risk of neutropenia throughout therapy. Transfusion-related excessive iron stores in children with sickle cell disease should be managed by a physician with expertise in chelation therapy owing to the risk of significant toxicity from available chelation therapies.

OTHER SICKLE CELL SYNDROMES
The most commonly occurring sickle cell syndromes besides HbSS are HbSC, HbSβ-thalassemia zero, and HbSβ-thalassemia+. The other syndromes—HbSD, HbSβ+40, HbS HPFH, and other variants—are much less common. Patients with HbSβ-thalassemia zero have a clinical phenotype similar to those with HbSS. HbSC does not polymerize like HbSS, but crystals of HbC interact with membrane ion transport, dehydrating red cells and inducing sickling. Children who have HbSC disease can experience the same symptoms and complications as those with severe HbSS disease, but the frequency of such experience is less. Children with HbSC also have increased incidence of retinopathy, chronic hypersplenism, splenectomy, and renal medullary carcinoma. The natural history of the other sickle cell syndromes is variable and difficult to predict because of the lack of systematic evaluation.

There is no validated model that can predict the clinical course of an individual with sickle cell disease. A patient with HbSC can have a more-severe clinical course than a patient with HbSS. Management of end-organ dysfunction in children with sickle cell syndromes requires the same general principles as managing patients with sickle cell anemia; however, each situation should be managed on a case-by-case basis and requires consultation with a pediatric hematologist.

ANTICIPATORY GUIDANCE
The 2 primary goals of pediatric care are to promote health and prevent disease. Children with sickle cell disease should receive general health maintenance as recommended for all children with special attention to the following disease specific guidance.

Spleen Palpation
Splenomegaly is a common complication of sickle cell anemia and splenic sequestration can be life-threatening. Parents and primary caregivers should be taught how to palpate the spleen to determine if the spleen is enlarging starting at the first visit with reinforcement at subsequent visits. Parents should also demonstrate spleen palpation to the provider.

Prophylactic Penicillin
Children with sickle cell anemia should receive prophylactic oral penicillin VK until at least 5 yr of age (125 mg twice a day up to age 3 yr, and then 250 mg twice a day thereafter). No established guidelines exist for penicillin prophylaxis beyond 5 yr of age, and some clinicians continue penicillin prophylaxis, whereas others recommend discontinuation. Continuation of penicillin prophylaxis should be continued beyond 5 yr of age in children with history of pneumococcal infection because of the increased risk of a recurrent infection. An alternative for children who are allergic to penicillin is erythromycin ethyl succinate 10 mg/kg twice a day.

Immunizations
In addition to penicillin prophylaxis, routine childhood immunizations, as well as the annual administration of influenza vaccine, are highly recommended. Children with sickle cell anemia develop functional asplenia and also require immunizations to protect against encapsulated organisms including additional pneumococcal and meningococcal vaccinations. Vaccination guidelines can be found at
Transcranial Doppler Ultrasound
Primary stroke prevention using TCD has resulted in a decrease in the prevalence of overt stroke among children with sickle cell anemia. Children with HbSS or HbS-β-thalassemia zero should be screened annually with TCD starting at age 2 yr. TCD is best performed when the child is quietly awake and in their usual state of health. TCD measurements may be falsely elevated in the setting of acute anemia or falsely low immediately after blood transfusions or if procedural sedation is used. Screening should occur annually from age 2-16 yr. Abnormal values should be repeated within 2-4 wk to identify patients at greatest risk of overt stroke. Conditional values should be repeated within 3 mo, and normal values repeated annually. Routine neuroimaging with MRI in asymptomatic patients is not currently recommended.

Hydroxyurea
Monitoring children on hydroxyurea is labor intensive. Hydroxyurea is a chemotherapeutic agent that requires the same level of nursing and physician oversight as any child with cancer receiving chemotherapy. The parents must be educated about the consequences of therapy, and when ill, children should be promptly evaluated. Complete blood count should be checked at least every 4 wk after initiation of therapy or any dose change to monitor for hematologic toxicity and then every 8 wk. Hydroxyurea should be temporarily discontinued and dose adjusted if the absolute neutrophil count falls below 2,000/µL or platelets fall below 80,000/µL. Hydroxyurea is a pregnancy class D medication and adolescents should be counseled regarding methods to prevent pregnancy while taking hydroxyurea. Close monitoring of the patient requires a commitment by the parents and patient, as well as diligence by a physician, to identify toxicity early.

Regular Blood Transfusion Therapy
At the initiation of blood transfusion therapy, children with sickle cell anemia should have testing to identify the presence of alloantibodies and red blood cell phenotyping, which is performed to identify the best matched blood. Children meeting criteria for chronic transfusion therapy should receive annual evaluation for transfusion transmitted infections including hepatitis B, hepatitis C, and human immunodeficiency virus (HIV). After receiving 100 mg/kg of red blood cell transfusions, regular assessments of iron overload should begin; usually periodic measurements of serum ferritin. For children requiring chelation therapy, an audiogram should be performed annually, as well as monitoring for organ toxicity, including liver function tests and endocrine evaluation of pituitary dysfunction because of iron deposition.

Pulmonary and Asthma Screening
Pulmonary complications of sickle cell disease are common and life-threatening. Asthma is common particularly in African-American children. As would be the case in all children, good clinical practice necessitates evaluation for asthma symptoms and asthma risk factors in children with sickle cell disease, particularly in light of the insurmountable evidence that asthma is associated with increased rate of sickle cell disease morbidity and mortality. All children should receive annual screening for signs and symptoms of lower airway disease, such as nighttime cough and exercise-induced cough. In children with symptoms consistent with lower airway disease, consider consultation with an asthma specialist. Pulse oximetry readings should be performed during well visits to identify children with abnormally low daytime oxygen saturations. For children with snoring and daytime somnolence, and symptoms associated with obstructive sleep apnea syndrome, referral to a sleep specialist should be considered.

Retinopathy
Effective therapy for retinopathy associated with sickle cell disease exists. Patients at highest risk for the development of retinopathy should receive annual screening by an ophthalmologist to identify vascular changes that would benefit from laser therapy. Although changes may occur earlier, children with sickle cell disease should begin annual screening at age 10 yr.

Renal
Sickle cell–associated renal disease, starts in infancy and may not become clinically manifested until adulthood. Screening for early signs of sickle nephropathy using urinalysis to identify proteinuria is recommended with annual albumin:creatinine ratios. The age to begin screening for proteinuria has not been defined, but some experts recommend screening annually after at least 10 yr of age if not sooner. If the albumin:creatinine ratio is elevated (>30 mg/g), it should be repeated with an early morning urine collection, and if still elevated, the patient should be referred to a pediatric nephrologist. Males with sickle cell disease should also receive counseling regarding the diagnosis and treatment of priapism. Because of the high frequency of enuresis beyond early childhood, approximately 9% of adolescents between 18 and 20 yr of age, parents and caregivers should be educated about the prolonged nature of enuresis in this disease. As is the case in the general population, obstructive sleep apnea syndrome is associated with an increased prevalence of enuresis in sickle cell disease. Unfortunately, no evidence-based therapies have been developed to treat enuresis in children and young adults with sickle cell disease. In children with enuresis who have symptoms and clinical features of obstructive sleep apnea syndrome, referral to sleep specialists for evaluation is recommended.

Echocardiography
Echocardiography has gained popularity as a screening tool to identify individuals with sickle cell disease who have pulmonary artery hypertension. No evidence currently exists that children with sickle cell disease and elevated tricuspid jet velocity above 2.5 cm/sec have an increased rate of mortality. Subsequent studies in adults with sickle cell disease have found the echocardiography to be insensitive at identifying individuals truly at risk for pulmonary hypertension, although an elevated tricuspid velocity measurement may still be a risk factor for premature death in adults with sickle cell disease. The current recommendation is to refer those with severe cardiopulmonary symptoms from associated pulmonary artery hypertension to pediatric cardiologist for a more formal evaluation.

462.2 Sickle Cell Trait (Hemoglobin AS)
Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

The prevalence of sickle cell trait varies throughout the world; in the United States, the incidence is 7-10% of African-Americans. Because all state newborn screening programs include sickle cell disease, for most children, sickle cell trait is first identified on their newborn screen. Communication of sickle cell trait status from infancy to young adulthood for the affected individual, family, and healthcare providers is often inconsistent and many young adults are unaware of their sickle cell trait status.

The production of HbS is influenced by the number of α-thalassemia genes present, and the amount of HbS. By definition among individuals with sickle cell trait, the HbS level is <50%. The life span of people with sickle cell trait is normal, and serious complications are extremely rare. The CBC is within the normal range (Fig. 462-5B). Hemoglobin analysis is diagnostic, revealing a predominance of HbA, typically >50%, and HbS <50%. Rare complications of sickle cell trait are associated with sudden death during rigorous exercise, splenic infarction at high altitude, hematuria, pyelonephritis, deep vein thrombosis, and susceptibility to eye injury with formation of a hyphema (Table 462-5). Renal

medullary carcinoma is also associated with sickle cell trait and occurs predominantly in young adults and children.

Children with sickle cell trait do not require limitations on physical activities. Sudden death in persons with sickle cell trait while exercising under extreme conditions is most likely associated with a second genetic factor and/or environmental factors, and not the presence of sickle cell trait itself. No causal pathway has been implicated for the presence of sickle cell trait and sudden death. All patients with sickle cell trait who participate in rigorous athletic activities should receive maximum hydration and appropriate rest during exertion, as would be the precautionary steps for all athletes, particularly when participating in hot humid conditions. The presence of sickle cell trait should never be a reason to exclude a person from athletic participation but rather should serve as an indication that prudent surveillance is necessary to ensure appropriate hydration and prevention of exhaustion from heat or other strenuous exercise. If athletes are to be screened for sickle cell trait, then appropriate genetic counseling should be provided, along with the knowledge that genetic information may provide opportunities to challenge paternity. Such situations are typically handled by a pediatrician or hematologist accustomed to providing both a balanced approach to genetic counseling and addressing the challenges about paternity.

462.3 Other Hemoglobinopathies

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

HEMOGLOBIN C

The mutation for HbC is at the same site as HbS, with substitution of lysine instead of valine for glutamine. In the United States, hemoglobin C trait (HbAC) occurs in 1:40 and homozygous...
Hemoglobin C disease (HbCC) occurs in 1-5,000 African-Americans. HbAC is asymptomatic. HbCC can result in mild anemia, splenomegaly, and cholelithiasis; rare cases of spontaneous splenic rupture have been reported. Sickness does not occur. This condition is usually diagnosed through newborn screening programs. HbC crystalizes, disrupting the red cell membrane, and HbC crystals may be visible on peripheral smear (see Fig. 462-5C).

**Hemoglobin E**

HbE is an abnormal hemoglobin resulting from a qualitative mutation in the β-globin gene and is the second most common globin mutation worldwide. Patients may have asymptomatic hemoglobin E trait (HbAE) or benign homozygous hemoglobin E disease (HbEE). Compound heterozygous hemoglobin E/β-thalassemia produces clinical phenotypes ranging from moderate to severe anemia depending on the β-thalassemia mutation. In California, HbE/β-thalassemia is found almost exclusively in persons of Southeast Asian descent, with a prevalence of 1:2,600 births.

**Hemoglobin D**

At least 16 variants of HbD exist. HbD-Punjab (Los Angeles) is a rare hemoglobin that is seen in 1-3% of Western Indians and in some Europeans with Asian-Indian ancestry and produces symptoms of sickle cell disease when present in combination with HbS. Heterozygous HbD or hemoglobin D trait (HbAD) is clinically silent. Heterozygous HbDD or HbD disease produces a mild to moderate anemia with splenomegaly.

**462.4 Unstable Hemoglobin Disorders**

At least 200 rare unstable hemoglobins have been identified; the most common is Hb Kolkata. Most patients seem to have de novo mutations rather than inherited hemoglobin disorders. The best studied unstable hemoglobins are the ones leading to hemoglobin denaturation from mutations affecting heme binding. The denatured hemoglobin can be visualized during severe hemolysis or after splenectomy as Heinz bodies. Unlike the Heinz bodies seen after toxic exposure, in unstable hemoglobins, Heinz bodies are present in reticulocytes and older red cells (see Fig. 462-5D). Heterozygotes are asymptomatic.

Children with homozygous gene mutations can present in early childhood with anemia and splenomegaly or with unexplained hemolytic anemia. Hemolysis is increased with febrile illness and with the ingestion of oxidant medications (similar to glucose-6-phosphate dehydrogenase [G6PD] deficiency) with some unstable hemoglobins. If the spleen is functional, the blood smear can appear almost normal or have only hypochromasia and basophilic stippling. A diagnosis may be made by demonstrating Heinz bodies, hemoglobin instability, or an abnormal hemoglobin analysis (although some unstable hemoglobins have normal mobility and are not detected on hemoglobin analysis).

Treatment is supportive. Transfusion may be required during hemolytic episodes in severe cases. Oxidative drugs should be avoided, and folate supplementation may be helpful if dietary deficiency is a concern. Splenectomy may be considered in patients requiring recurrent transfusion or demonstrating poor growth, but the complications of splenectomy, including bacterial sepsis, risk of thrombosis, and the possibility of developing pulmonary hypertension, should be considered before surgery.

**462.5 Abnormal Hemoglobins with Increased Oxygen Affinity**

More than 110 high-affinity hemoglobins have been characterized. These mutations affect the state of hemoglobin configuration during oxygenation and deoxygenation. Hemoglobin changes structure when in the oxygenated versus the deoxygenated state. The deoxygenated state is termed the T (tense) state and is stabilized by 2,3-diphosphoglycerate. When fully oxygenated, hemoglobin assumes the R (relaxed) state. The exact molecular interactions between these 2 states are unknown. High-affinity hemoglobins contain mutations that either stabilize the R form or destabilize the T form. The interactions between the R and T forms are complex, and the mechanisms of the mutations are not known. In most cases, the high-affinity hemoglobins can be identified by hemoglobin analysis; approximately 20% must be characterized under controlled conditions where measurements are obtained with the P50 lowered to 9-21 mm Hg (normal: 23-29 mm Hg). The decreased P50 in these hemoglobins leads to an erythrocytosis with hemoglobin levels of 17-20 g/dL. Levels of erythropoietin and 2,3-diphosphoglycerate are normal. Patients are usually asymptomatic and do not need phlebotomy. If phlebotomy is performed, oxygen delivery could be problematic owing to the reduced number of hemoglobin molecules to carry oxygen.

**462.6 Abnormal Hemoglobins Causing Cyanosis**

Abnormal hemoglobins causing cyanosis, also called structural met-hemoglobinemias, are rare. They are referred to as “M-hemoglobins” and represent a group of hemoglobin variants which result from point mutations in one of the globin chains, α, β, or γ located in the heme pocket. Thirteen known variants exist. These unstable hemoglobins lead to hemolytic anemia, most pronounced when the β-globin gene is affected. Clinically, these children are cyanotic from birth, without other signs or symptoms of disease, if the mutation is in the α-globin gene (HbM Boston, HbM Iwate, Hb Auckland). Infants with β-globin mutations become cyanotic later in infancy after the fetal hemoglobin switch (HbM Saskatoon, HbM Chile, Hb Milwaukee 1 and 2). γ-chain mutations (HbF-M Fort Riley, HbF-M Osaka, HbF Cincinn nati, HbF Circleville, HbF Toms River, HbF Viseu) are all transient, presenting with cyanosis at birth, which resolves during the neonatal period after HbF production discontinues. The abnormal M hemoglobins exhibit autosomal dominant inheritance and are diagnosed by hemoglobin analysis. HbM variants may be not be isolated reliably using hemoglobin analysis (HPLC or isoelectric focusing [IEF]), consequently diagnostic confirmation may require DNA sequencing or mass spectrometry. There is no specific treatment and affected patients do not respond to treatments used for enzyme-deficient methemoglobinemia. Beyond cyanosis, individuals are otherwise asymptomatic and do not require additional monitoring. Children with the β-globin form should avoid oxidant drugs. Individuals with all forms have a normal life expectancy and pregnancy course.

Low-affinity hemoglobins have less cyanosis than the M hemoglobin. The amino acid substitutions stabilize the oxymyoglobin and lead to decreased oxygen saturation. The best characterized are Hb Kansas, Hb Beth Israel, and Hb Denver. Hemoglobin analysis (IEF and HPLC techniques) may be normal in affected individuals. When clinically suspected, oxygen affinity studies reveal a right-shifted dissociation curve and heat testing demonstrates unstable hemoglobin. Children present with mild cyanosis only.

**462.7 Hereditary Methemoglobinemia**

Hereditary methemoglobinemia is a clinical syndrome caused by an increase in the serum concentration of methemoglobin either as a result of congenital changes in hemoglobin synthesis or of metabolism.
leading to imbalances in reduction and oxidation of hemoglobin. The iron molecule in hemoglobin is normally in the ferrous state (Fe\(^{2+}\)), which is essential for oxygen transport. Under physiologic conditions there is a slow, constant loss of electrons to released oxygen, and the ferric (Fe\(^{3+}\)) form combines with water, producing methemoglobin (MetHb). The newly formed MetHb has a reduced ability to bind oxygen.

Two pathways for MetHb reduction exist. The physiologic and predominant pathway is a reduced form of nicotinamide adenine dinucleotide (NADH)-dependent reaction catalyzed by cytochrome b5 reductase. This mechanism is >100-fold more efficient than the production of MetHb. The alternate pathway utilizes nicotinamide adenine dinucleotide phosphate generated by G6PD in the hexose monophosphate shunt and requires an extrinsic electron acceptor to be activated (i.e., methylene blue, ascorbic acid, riboflavin). In normal individuals, oxidation of hemoglobin to MetHb occurs at a slow rate, 0.5-3%, which is countered by MetHb reduction to maintain a steady state of 1% MetHb.

MetHb may be increased in the red cell owing to exposure to toxic substances or to absence of reductive pathways, such as NADH-cytochrome b5 reductase deficiency. Toxic methemoglobinemia is much more common than hereditary methemoglobinemia (Table 462-6). Infants are exceptionally vulnerable to hemoglobin oxidation because their erythrocytes have half the amount of cytochrome b5 reductase than hemoglobin A, and the more alkaline infant gastrointestinal tract promotes the growth of nitrite-producing Gram-negative bacteria. When MetHb levels are >1.5 g/24 hr, cyanosis is visible (15% MetHb); a level of 70% MetHb is lethal. The MetHb level is usually reported as a percentage of normal hemoglobin, and the toxic level is lower at a lower hemoglobin level. Methemoglobinemia has been described in infants who ingested foods and water high in nitrates, who were exposed to aniline teething gels or other chemicals, and in some infants with severe gastroenteritis and acidosis. Methemoglobin can color the blood brown (Fig. 462-6).

### 462.8 Hereditary Methemoglobinemia with Deficiency of NADH Cytochrome b5 Reductase

Michael R. DeBaun, Allison Grimes, Melissa J. Frei-Jones, and Elliott P. Vichinsky

The first reported inherited disorder causing methemoglobinemia resulted from an enzymatic deficiency of NADH cytochrome b5 reductase, which was classified into 2 distinct phenotypes. In type I, the most common form, the deficiency of NADH cytochrome b5 activity is found only in erythrocytes, with other cell types unaffected. In type II, the enzyme deficiency is present in all tissues and results in more significant symptoms beginning in infancy with encephalopathy, mental retardation, spasticity, microcephaly, and growth retardation with death most often by 2 yr of age. Both types exhibit an autosomal recessive inheritance pattern.

Clinically, cyanosis varies in intensity with season and diet. The time of cyanosis onset also varies; in some patients it appears at birth, in others as late as adolescence. Although as much as 50% of the total circulating hemoglobin may be in the form of nonfunctional MetHb, little or no cardiorespiratory distress occurs in these patients, except on exertion.

Daily oral treatment with ascorbic acid (200-500 mg/day in divided doses) gradually reduces the MetHb to approximately 10% of the total.

pigment and alleviates the cyanosis as long as therapy is continued. Chronic high doses of ascorbic acid have been associated with hyperoxaluria and renal stone formation. Ascorbic acid should not be used to treat toxic methemoglobinemia. When immediately available, poison control should be contacted to verify the most up-to-date therapeutic strategies. Like ascorbic acid, riboflavin utilizes the alternate pathway of MetHb reduction and is most effective when given in high doses (400 mg once daily). Methylene blue, administered intravenously (1-2 mg/kg initially), is used to treat toxic methemoglobinemia. An oral dose can be administered (100-300 mg PO per day) as maintenance therapy.

Methylene blue should not be used in patients with G6PD deficiency. This treatment is ineffective and can cause severe oxidative hemolysis. In the event that methylene blue is given to a patient with G6PD deficiency, there will be no improvement in symptoms and marked hemolysis has been reported within 24 hr of administration. Because G6PD deficiency status is rarely known at the time of treatment, a careful history should be elicited. When the history is negative for symptoms of G6PD deficiency, treatment with methylene blue should be initiated judiciously, and the patient should be closely monitored for improvement.

462.9 Syndromes of Hereditary Persistence of Fetal Hemoglobin

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

HPFH syndromes are a form of thalassemia; mutations are associated with a decrease in the production of either or both β- and δ-globins. There is an imbalance in the αnon-α synthetic ratio (see Chapter 462.9) characteristic of thalassemia. More than 20 variants of HPFH have been described. They are deletional, ∆β° (Black, Ghanaian, Italian), nondeletional (Tunisian, Japanese, Australian), linked to the β-globin–gene cluster (British, Italian-Chinese, Black), or unlinked to the β-globin–gene cluster (Atlanta, Czech, Seattle). The ∆β° forms have deletions of the entire δ- and β-globin gene sequences, and the most common form in the United States is the Black (HPFH 1) variant. As a result of the δ and β gene deletions, there is production only of γ-globin and formation of HbF. In the homozygous form, no manifestations of thalassemia are present. There is only HbF with very mild anemia and slight microcytosis. When inherited with other variant hemoglobins, HbF is elevated into the 20-30% range; when inherited with HbS, there is an amelioration of sickle cell disease with fewer complications.

462.10 Thalassemia Syndromes

Michael R. DeBaun, Melissa J. Frei-Jones, and Elliott P. Vichinsky

Thalassemia refers to a group of genetic disorders of globin chain production in which there is an imbalance between the α-globin and β-globin chain production. β-Thalassemia syndromes result from a decrease in β-globin chains, which results in a relative excess of α-globin chains. β°-Thalassemia refers to the absence of production of the β-globin. When patients are homozygous for the β-thalassemia gene, they cannot make any normal β chains (HbA). β°-Thalassemia indicates a mutation that makes decreased amounts of normal β-globin, but it is still present (HbA). β°-Thalassemia syndromes are more severe than β°-thalassemia syndromes, but there is significant variability between the genotype and phenotype. β-Thalassemia major refers to the severe β-thalassemia patient who requires early transfusion therapy and often is homozygous for β° mutations. β-Thalassemia intermedia is a clinical diagnosis of a patient with a less-severe clinical phenotype that usually does not require transfusion therapy in childhood. Many of these patients have at least 1 β°-thalassemia mutation. β-Thalassemia syndromes usually require a β-thalassemia mutation in both β-globin genes. Carriers with a single β-globin mutation are generally asymptomatic, except for microcytosis and mild anemia. In α-thalassemia, there is an absence or reduction in α-globin production. Normal individuals have 4 α-globin genes. The more genes affected, the more severe the disease. An α°-mutation indicates no α-chains produced from that gene. An α° mutation produces a decreased amount of α-globin chain. The primary pathology in the thalassemia syndromes stems from the quantity of globin produced, whereas the primary pathology in sickle cell disease is related to the quality of β-globin produced.

EPIDEMIOLOGY

There are >200 different mutations resulting in absent or decreased globin production. Although most are rare, the 20 most common abnormal alleles constitute 80% of the known thalassemias worldwide; 3% of the world’s population carries alleles for β-thalassemia, and in Southeast Asia 5-10% of the population carry alleles for α-thalassemia. In a particular region, there are fewer common alleles. In the United States, an estimated 2,000 persons have β-thalassemia major.

PATHOPHYSIOLOGY

Two related features contribute to the sequelae of β-thalassemia major: inadequate β-globin gene production leading to decreased levels of normal hemoglobin (HbA) and unbalanced α- and β-globin chain production. In β-thalassemia major, α-globin chains are in excess to non-α-globin chains, and α-globin tetramers (α4) are formed and appear as red cell inclusions. The free α-globin chains and inclusions are very unstable, precipitate in red cell precursors, damage the red cell membrane, and shorten red cell survival leading to anemia and increased erythroid production. Table 462-7 shows selected features of thalassemia. This results in a marked increase in erythropoiesis with early erythroid precursor death in the bone marrow. Clinically, this is characterized by a lack of maturation of erythrocytes and an inappropriately low reticulocyte count. This ineffective erythropoiesis and the compensatory massive marrow expansion with erythroid hyperactivity characterize β-thalassemia. Because the β°-thalassemia patient cannot make HbA, the α-chains combine with γ-chains, resulting in HbF (α2γ2), being the dominant hemoglobin. In addition to the natural survival effect, the γ-globin chains may be produced in increased amounts, which is regulated by genetic polymorphisms. δ-Chain synthesis is not usually affected in β-thalassemia or β-thalassemia trait, and, therefore, patients have a relative or absolute increase in HbA2 production (α2δ2).

In the α-thalassemia syndromes, 2 genes with 2 maternal and 2 paternal alleles control α-globin production, which varies from complete absence (hydrops fetalis) to only slightly reduced (α-thalassemia silent carrier). In the α-thalassemia syndromes, an excess of β- and γ-globin chains are produced. These excess chains form Bart hemoglobin (γγ) in fetal life and HbH (βδ) after birth. These abnormal tetramers are nonfunctional hemoglobin with very high oxygen affinity. They do not transport oxygen and result in extravascular hemolysis. A fetus with the most severe form of α-thalassemia (hydrops fetalis) develops in utero anemia and fetal loss because HbF production requires sufficient amounts of α-globin. In contrast, infants with β-thalassemia major become symptomatic only after birth when HbA predominates and insufficient β-globin production manifests in clinical symptoms.

HOMOZYGOUS β-TALASSEMA

(THALASSEMA MAJOR, COLEY ANEMIA)

Clinical Manifestations

If not treated, children with homozygous β-thalassemia usually become symptomatic from progressive hemolytic anemia, with profound weakness and cardiac decompensation during the 2nd 6 mo of life. Depending on the mutation and degree of fetal hemoglobin production, transfusions in β-thalassemia major are necessary beginning in the 2nd mo to 2nd yr of life, but rarely later. The decision to transfuse is multifactorial but is not determined solely by the degree of anemia. The developing signs of ineffective erythropoiesis such as growth
failure, bone deformities secondary to marrow expansion, hepatosplenomegaly are important variables in determining transfusion initiation.

The classic presentation of children with severe disease includes thalassemic facies (maxilla hyperplasia, flat nasal bridge, frontal bossing), pathologic bone fractures, marked hepatosplenomegaly, and cachexia and is now primarily seen in countries without access to chronic transfusion therapy. Occasionally, patients with moderate anemia develop these features because of severe compensatory ineffective erythropoiesis.

In nontransfused patients with severe ineffective erythropoiesis, marked splenomegaly can develop with hypersplenism and abdominal symptoms. The features of ineffective erythropoiesis include expanded medullary spaces (with massive expansion of the marrow of the face and skull producing the characteristic thalassemic facies), extramedullary hematopoiesis, and higher metabolic needs (Fig. 462-7). The clinical presentation of severe thalassemia is usually aggravated by transplantation and reduces the complications of severe thalassemia. Transfusion-induced hemosiderosis becomes the major clinical complication of transfusion-dependent thalassemia. Each mL of packed red cells contains 1 mg of iron. Physiologically, there is no mechanism to eliminate excess body iron. Iron is initially deposited in the liver. Liver hemosiderosis develops after 1 yr of chronic transfusion therapy and is followed by iron deposition in the endocrine system. This leads to a high rate of hypothyroidism, hypogonadotrophic gonadism, growth hormone deficiency, hypoparathyroidism, and diabetes mellitus. After 10 yr of transfusion, cardiac dysfunction secondary to hemosiderosis begins. Eventually, most patients not receiving adequate iron chelation therapy die from cardiac failure and/or cardiac arrhythmias secondary to hemosiderosis. Hemosiderosis-induced morbidity can be prevented by adequate iron chelation therapy.

### Laboratory Findings

In the United States, some children with β-thalassemia major will be identified on newborn screening as a result of the detection of only HbF on hemoglobin electrophoresis. However, the ethnicity and the mutations associated with transfusion-dependent thalassemia in United States have dramatically changed. Many of the patients have diverse mutations, such as HbE thalassemia, which may not be identified or followed up by a newborn screening program. HbE in the newborn may be a very common benign mutation caused by homozygous HbEE or an uncommon severe HbE β-thalassemia. The lack of standardized neonatal diagnosis of thalassemia disorders requires close follow-up of newborns with unclear thalassemia mutations and/or babies from high-risk ethnic groups.

Infants with serious β-thalassemia disorders have a progressive anemia after the newborn period. Microcytosis (MCV), hypochromia (MCH), and targeting characteristic the red cells. Nucleated red cells, marked anisopoikilocytosis, and a relative reticulocytopenia are typically seen (see Fig. 462-5E). The hemoglobin level falls progressively to <6 g/dL unless transfusions are given. The reticulocyte count is

commonly <8% and is inappropriately low when compared to the degree of anemia as a result of ineffective erythropoiesis. The unconjugated serum bilirubin level is usually elevated, but other chemistries may be normal early on. Even if the child does not receive transfusions, iron eventually accumulates with elevated serum ferritin and transferrin saturation. Bone marrow hyperplasia can be seen on radiographs (see Fig. 462-7).

Early definitive diagnosis is recommended. Newborn screening techniques such as hemoglobin electrophoresis is not definitive. DNA diagnosis of the β-thalassemia mutation, along with testing for common genetic modifiers of the clinical phenotype, is recommended. Coinheritance of an α-thalassemia mutation is common, and it decreases the severity of the β-thalassemia disease. Some patients' mutations cannot be diagnosed by standard electrophoresis or common DNA probes. Referral of the samples to a tertiary laboratory along with parental and family testing are indicated. Following the definitive diagnosis, families should undergo detailed counseling.

Management and Treatment of Thalassemia

Transfusion Therapy

Before initiating chronic transfusions, the diagnosis of transfusion dependent β-thalassemia should be confirmed by both clinical and laboratory parameters. β-Thalassemia major is a clinical diagnosis that requires the integration of laboratory findings and the clinical course. Of patients with homozygous β-thalassemia (the most severe mutations), 15-20% may have a clinical course that is phenotypically consistent with thalassemia intermedia. In contrast, 25% of patients with homozygous β-thalassemia, typically a more benign genotype, may become transfusion-dependent thalassemia major. Transient clinical events, such as a sudden fall in hemoglobin secondary to an episode of parvovirus requiring transfusion, do not necessarily indicate the patient is a transfusion-dependent patient. The long-term observation of the clinical characteristics, such as growth, bony changes, and hemoglobin, are necessary to determine chronic transfusion therapy.

Guidelines for Transfusion Therapy

Patients at risk for transfusion therapy should have an extended red cell phenotype and/or genotype. Patients should receive red cells depleted of leukocytes and matched for, at least, D, C, c, E, e, and Kell antigens. Cytomegalovirus-negative units are indicated in stem cell transplantation candidates. Transfusions should generally be given at intervals of 3-4 wk, with the goal being to maintain a pretransfusion hemoglobin level of 9.5-10.5 g/dL. Ongoing monitoring for transfusion-associated transmitted infections (hepatitis A, hepatitis B, hepatitis C, HIV), alloimmunization, annual blood transfusion requirements, and transfusion reactions is essential.

Iron Overload Monitoring

Excessive iron stores from transfusion cause many of the complications of β-thalassemia major. Accurate assessment of excessive iron stores is essential to optimal therapy. Serial serum ferritin levels are a useful screening technique in assessing iron balance trends, but results may not accurately predict quantitative iron stores. Undertreatment or overtreatment of presumed excessive iron stores can occur in managing a patient based on serum ferritin alone. Noninvasive measurement of quantitative organ injury is rapidly improving the treatment of iron overload. Quantitative measurement of liver iron and cardiac iron are standard and measurement of pancreatic and gonadal iron may be available soon. This technology, in collaboration with access to multiple chelators, will enable targeted chelation therapy for patients with organ specific hemosiderosis before the onset of overt organ failure. Available data suggests integration of these imaging technologies with chelation therapy may prevent heart failure, diabetes, and other pending organ dysfunction.

Quantitative liver iron by approved MRI technology is the best indicator of total-body iron stores and should be obtained in chronically transfused patients after chronic transfusion therapy has initiated. The liver iron results will help guide the chelation regimen. Quantitative cardiac iron, determined by T2* MRI cardiac software, should be obtained after 2 yr of transfusion therapy. It is not uncommon to have a discrepancy between the liver iron and the heart iron because of different rates of tissue loading and cardiac chelation efficacy.

Chelation Therapy

Iron-chelation therapy should start as soon as the patient becomes significantly iron overloaded. In general, this occurs after 1 yr of transfusion therapy and correlates with the serum ferritin >1,000 ng/mL and/or a liver iron concentration of >2,500 µg/g dry weight.

There are 3 available iron chelators (deferoxamine, deferasirox, and deferiprone); each varies in its route of administration, pharmacokinetics, adverse events, and efficacy. Many patients require combination chelation therapy at various points in their illness. The overall goal is to prevent hemosiderosis-induced tissue injury and avoid chelation toxicity. This requires close monitoring of the patients. In general, chelation toxicity increases as iron stores decrease.

Deferoxamine (Desferal) is the most studied iron chelator; it has an excellent safety and efficacy profile. It requires subcutaneous, or intravenous, administration because of a half-life of less than 30 min, necessitating administration of at least 8 hr daily, 5-7 days/wk. Deferoxamine is initially started at 20 mg/kg and can be increased to 60 mg/kg in heavily iron-overloaded patients. The major problem with deferoxamine is noncompliance because of the route of administration.
Cardiac disease is the major cause of death in thalassemia. Splenectomy may be required in thalassemia patients who develop hypersplenism. These patients have a falling steady state hemoglobin and/or a rising transfusion requirement. Overall, splenectomy is less frequently used as a therapeutic option. There is an increased recognition of serious adverse effects of splenectomy beyond infection risk. In thalassemia intermedia, splenectomized patients have a marked increased risk of venous thrombosis, pulmonary hypertension, leg ulcers, and silent cerebral infarction compared to nonsplenectomized patients. All patients should be fully immunized against encapsulated bacteria and should be on long-term penicillin prophylaxis with appropriate instructions regarding fever management. Prophylactic penicillin should be administered posttransplantation to prevent sepsis, and families need to be educated on the risk of fever and sepsis.

**Preventative Monitoring of Thalassemia Patients**

**Cardiac.** Cardiac disease is the major cause of death in thalassemia. Serial echocardiograms should be monitored to evaluate cardiac function and pulmonary artery pressure. Pulmonary hypertension frequently occurs in non-transfused thalassemia patients and may be an indication for transfusion therapy. After 8 yr of chronic transfusion therapy, cardiac hemosiderosis may occur; consequently, cardiac T2* MRI imaging studies are recommended. Patients with cardiac hemosiderosis and decreasing cardiac ejection fraction require intensive combination chelation therapy.

**Endocrine.** Endocrine function progressively declines with age secondary to hemosiderosis and nutritional deficiencies. Iron deposition in the pituitary and endocrine organs can result in multiple endocrinopathies, including hypothyroidism, growth hormone deficiency, delayed puberty, and hypoparathyroidism, diabetes mellitus, osteopenia, and adrenal insufficiency. Monitoring for endocrine dysfunction starts early, around 5 yr of age, or after at least 3 yr of chronic transfusions. All children require monitoring of their height, weight, and sitting height semi-annually. Nutritional assessments are required. Most patients need vitamin D, calcium, vitamin B, vitamin C, and zinc replacement. Fertility is a growing concern among patients and should be assessed routinely.

**Psychosocial Support.** Thalassemia imposes major disruption in the family unit and significant obstacles to normal development. Culturally sensitive anticipatory counseling is necessary, and the early use of child life services decreases psychological trauma of therapy. Early social service consultation to address financial and social issues is mandatory.

**OTHER 𝛽-THALASSEMIA SYNDROMES**

**Nontransfusion-Dependent Thalassemia:**

**𝛽-Thalassemia Intermida**

The 𝛽-thalassemia syndromes are characterized by decreased production of 𝛽-globin chains of HbA. There are 200-300 𝛽-thalassemia alleles that have now been characterized. These mutations can affect any step in the transcription of 𝛽-globin genes. As discussed, 𝛽⁺-thalassemia is absent production of normal 𝛽-chains, and production of 𝛽⁺ is decreased. Some 𝛽-thalassemia mutations have structural mutations such as HbE. Others, such as 𝛽⁺-thalassemia or HPPH, are variants of 𝛽-thalassemia that have decreased production of 𝛽-globin gene with increased compensation of HbF. Because phenotypic correlation with genotype is variable, 𝛽-thalassemia patients are largely classified by their clinical spectrum. Transfusion-dependent thalassemia, or thalassemia major, is the most severe group. Nontransfusion-dependent thalassemia intermedia include a spectrum of patients who initially are not chronically transfused in infancy but may be sporadically transfused throughout their lifetime. The major determining characteristic of these patients is less 𝛼-𝛽-globin chain imbalance than observed in thalassemia major. Sometimes, genetic modifiers alter the primary mutation severity and improve the globin chain imbalance. Coinheritance of 𝛼-thalassemia trait or polymorphisms of globin promoters such as BCL11 may convert a thalassemia major patient to a nontransfusion-dependent thalassemia intermedia patient. HbE 𝛽-thalassemia is a common cause of both transfusion-dependent and nontransfusion-dependent thalassemia. These secondary genetic modifiers play a role in altering the severity of this disorder. Occasionally, patients with a single 𝛽-thalassemia mutation or autosomal dominant 𝛽-thalassemia trait have clinical features of thalassemia intermedia, or nontransfusion-dependent thalassemia. Genetic studies of these patients often uncover a coinheritance of genetic modifiers that worsen the condition such as 𝛼-gene triplication or an unstable 𝛽-globin mutation.
Thalassemia intermedia patients have significant ineffective erythropoiesis that leads to microcytic anemia with hemoglobin of approximately 7 g/dL (range: 6-10 g/dL). These patients have some of the complications characterized in transfused thalassemia major patients, but the severity varies depending on the degree of ineffective erythropoiesis. They can develop medullary hyperplasia, hepatosplenomegaly, hematopoietic pseudotumors, pulmonary hypertension, thrombotic events, and growth failure. Many patients develop hemosiderosis secondary to increased gastrointestinal absorption of iron requiring chelation. Extramedullary hemopoiesis can occur in the vertebral canal, compressing the spinal cord and causing neurologic symptoms; the latter is a medical emergency requiring immediate local radiation therapy to halt erythropoiesis. Transfusions are indicated in thalassemia intermedia patients with significant clinical morbidity.

*Thalassemia trait is often misdiagnosed as iron deficiency in children because the two produce similar hematologic abnormalities on CBC, and iron deficiency is much more prevalent.* A short course of iron and reevaluation is all that is required to identify children who will need further evaluation. Children who have β-thalassemia trait have a persistently normal red cell distribution width and low mean corpuscular volume (MCV), whereas patients with iron deficiency develop an elevated red cell distribution width with treatment. On hemoglobin analysis, they have an elevated HbF and usually increased levels of HbA2. There are “silent” forms of β-thalassemia trait, and if the family history is suggestive, further studies may be indicated.

### α-THALASSEmia SYNDROMES

The same evolutionary pressures that produced β-thalassemia and sickle cell disease produced α-thalassemia. Infants are identified in the newborn period by the increased production of Bart hemoglobin (γγ) during fetal life and its presence at birth. The α-thalassemia syndromes occur most commonly in Southeast Asia. Deletion mutations are common in α-thalassemia. In addition to deletional mutations, there are nondeletional α-globin gene mutations, the most common being Constant Spring (αα−αα); these mutations cause a more severe anemia and clinical course than the deletional mutations. There are 4 α-globin gene alleles and 4 deletional α-thalassemia phenotypes. The different phenotypes in α-thalassemia largely result from whether one (αα-thalassemia) or both (αα-thalassemia) α-globin genes are deleted in each of the 2 loci.

The deletion of 1 α-globin gene allele (silent trait) is not identifiable hematologically. Specifically, no alterations are noted in the MCV and mean corpuscular hemoglobin. Persons with this deletion are usually diagnosed after the birth of a child with a 2-gene deletion or HbH (ββββ), but some newborn screening programs report even low concentrations of Hb Bart. During the newborn period, <3% Hb Bart is observed. The deletion of 1 α-globin gene allele is common in African-Americans.

The deletion of 2 α-globin gene alleles results in α-thalassemia trait. The α-globin alleles can be lost in a *trans*-(αα−αα) or *cis*-(αααα−αααα) configuration. The *trans* or *cis* mutations can combine with other mutations and lead to HbH or α-thalassemia major. In persons from Africa or of African descent, the most common α-globin deletions are in the *trans* configuration; whereas, in persons from or descended from Asia or the Mediterranean region, *cis* deletions are most common.

α-Thalassemia trait manifest as a microcytic anemia that can be mistaken for iron-deficiency anemia (see Fig. 462-5F). The hemoglobin analysis is normal, except during the newborn period, when Hb Bart is commonly <8% but >3%. Children with a deletion of 2 α-globin alleles are commonly thought to have iron deficiency, given the presence of both low MCV and mean corpuscular hemoglobin. The simplest approach to distinguish between iron deficiency and α-thalassemia trait is with a good dietary history. Children with iron-deficiency anemia often have a diet that is low in iron and drink significant amount of cow’s milk. Alternatively, a brief course of iron supplementation along with monitoring of erythrocyte parameters might confirm the diagnosis of iron deficiency. If both parents of a child diagnosed with α-thalassemia trait are carriers, they are at risk for a future hydrops fetalis pregnancy. Thus, family screening and genetic counseling are indicated.

The deletion of 3 α-globin gene alleles leads to the diagnosis of HbH disease. A more severe form of HbH disease may be caused by a nondeletional α-globin mutation with 2 allele deletions. HbH Constant Spring (αααα−αααα) is the most common type of nondeletional HbH disease.

In California, where a large population of persons of Asian descent resides, approximately 1:10,000 of all newborns have HbH disease. The simplest manner of diagnosing HbH disease is during the newborn period, when excess in γ-tetramers are present and Hb Bart is commonly >25%. Obtaining supporting evidence from the parents is also necessary. Later in childhood, there is an excess of β-globin chain tetramers that results in HbH. A definitive diagnosis of HbH disease requires DNA analysis with supporting evidence. Brilliant cresyl blue can stain HbH, but it is rarely used for diagnosis. Patients with HbH disease have a marked microcytosis, anemia, mild splenomegaly, and, occasionally, scleral icterus or cholelithiasis. Chronic transfusion is not commonly required for therapy because the range of hemoglobin is 7-11 g/dL, with MCV 51-73 fl, but intermittent transfusions for worsening anemia may be needed.

The deletion of all 4 α-globin gene alleles causes profound anemia during fetal life, resulting in hydrops fetalis; the ζ-globin gene must be present for fetal survival. There are no normal hemoglobins present at birth (primarily Hb Bart, with Hb Gower 1, Gower 2, and Portland). If the fetus survives, immediate exchange transfusion is indicated. These infants with severe α-thalassemia are transfusion dependent, and hematopoietic stem cell transplantation is the only cure.

Treatment of HbH disease requires ongoing monitoring of growth and organ dysfunction. Dietary supplement with folate and multivitamins without iron is indicated. Older patients may develop decreased bone density with calcium and vitamin D deficiency. Iron supplementation should be avoided. Intermittent transfusion requirements during child development and infection may occur, particularly in nondele- tional HbH. Splenectomy is occasionally indicated and because of the high risk of postsplenectomy thrombosis, aspirin or other anticoagu- lant therapy following splenectomy should be considered. Hemosiderosis, secondary to gastrointestinal iron absorption and/or transfusion exposure, may develop in older patients and require therapy. Because HbH is an unstable hemoglobin sensitive to oxidative injury, oxidative medications should be avoided. At-risk couples for hydrops fetalis should be identified and offered molecular diagnosis on fetal tissue obtained early in pregnancy. Later in pregnancy, intrauterine transfusion can improve fetal survival, but chronic transfusion therapy or bone marrow transplantation for survivors will be required.

*Bibliography is available at Expert Consult.*
Bibliography

463.1 Pyruvate Kinase Deficiency

George B. Segel

Congenital hemolytic anemia occurs in persons homozygous or compound heterozygous for autosomal recessive genes that cause either a marked reduction in red blood cell (RBC) pyruvate kinase (PK) or production of an abnormal enzyme with decreased activity resulting in impaired conversion of phosphoenolpyruvate to pyruvate. Generation of adenosine triphosphate (ATP) within RBCs at this step is impaired, and low levels of ATP, pyruvate, and the oxidized form
of nicotinamide adenine dinucleotide (NAD\(^+\)) are found (Fig. 463-1). The concentration of 2,3-diphosphoglycerate is increased; this isomer is beneficial in facilitating oxygen release from hemoglobin but detrimental in inhibiting hexokinase and enzymes of the hexose monophosphate shunt. In addition, an unexplained decrease occurs in the sum of the adenine (ATP, adenosine diphosphate, and adenosine phosphate) nucleotides, further impairing glycolysis. As a consequence of reduced ATP, RBCs cannot maintain their potassium and water content; the cells become rigid, and their life span is considerably decreased.

**ETIOLOGY**

There are 2 mammalian PK genes, but only the PKLR gene is expressed in red cells. The human PKLR gene is located on chromosome 1q21. More than 180 mutations are reported in this structural gene, which codes for a 574–amino-acid protein that forms a functional tetramer. These mutations include missense, splice site, and insertion–deletion alterations, and there is some correlation of the type, location, and amino acid substitution with disease severity. Most affected patients are compound heterozygotes for 2 different PK gene defects. The many possible combinations likely account for the variability in clinical severity. The mutations 1456 C to T and 1529 G to A are the most common mutations in the white population.

**CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS**

The clinical manifestations of PK deficiency vary from severe neonatal hemolytic anemia to mild, well-compensated hemolysis first noted in adulthood. Severe jaundice and anemia may occur in the neonatal period, and kernicterus has been reported. The hemolysis in older children and adults varies in severity, with hemoglobin values ranging from 8-12 g/dL associated with some pallor, jaundice, and splenomegaly. Patients with these findings usually do not require transfusion. A severe form of the disease has a relatively high incidence among the Amish of the midwestern United States. PK deficiency may possibly provide protection against falciparum malaria.

Polychromatophilia and mild macrocytosis reflect the elevated reticulocyte count. Spherocytes are uncommon, but a few spiculated pyknotic cells may be found. Diagnosis relies on demonstration of a marked reduction of RBC PK activity or an increase in the Michaelis-Menten dissociation constant (\(K_m\)) for its substrate, phosphoenolpyruvate (high \(K_m\) variant). Other RBC enzyme activity is normal or elevated, reflecting the reticulocytosis. No abnormalities of hemoglobin are noted. The white cells have normal PK activity and must be rigorously excluded from the red cell hemolysates used to measure PK activity. Heterozygous carriers usually have moderately reduced levels of PK activity.

**TREATMENT**

Phototherapy and exchange transfusions may be indicated for hyperbilirubinemia in newborns. Transfusions of packed RBCs are necessary for severe anemia or for aplastic crises. If the anemia is consistently severe and frequent transfusions are required, iron chelation may be necessary, and splenectomy should be performed after the child is 5-6 yr of age. Although it is not curative, splenectomy may be followed by higher hemoglobin levels and by strikingly high (30-60%) reticulocyte counts. Death resulting from overwhelming pneumococcal sepsis has followed splenectomy; thus, immunization with vaccines for encapsulated organisms should be given before splenectomy, and prophylactic penicillin should be administered after the procedure.
463.2 Other Glycolytic Enzyme Deficiencies

George B. Segel

Chronic nonspherocytic hemolytic anemias of varying severity have been associated with deficiencies of other enzymes in the glycolytic pathway, including hexokinase, glucose phosphate isomerase, and aldolase, which are inherited as autosomal recessive disorders. **Phosphofructokinase deficiency**, which occurs primarily in Ashkenazi Jews in the United States, results in hemolysis associated with a myopathy classified as glycogen storage disease type VII (see Chapter 87.1). Clinically, hemolytic anemia is complicated by muscle weakness, exercise intolerance, cramps, and possibly myoglobinuria. Enzyme assays for phosphofructokinase yield low values for RBCs and muscle.

**Triose phosphate isomerase deficiency** is an autosomal recessive disorder affecting many systems. Affected patients have hemolytic anemia, cardiac abnormalities, and lower motor neuron and pyramidal tract impairment, with or without evidence of cerebral impairment. They usually die in early childhood. The gene for triose phosphate isomerase has been cloned and sequenced and is located on chromosome 12.

**Phosphoglycerate kinase** (PGK) is the first ATP-generating step in glycolysis. At least 23 kindreds with PGK deficiency have been described. PGK is the only glycolytic enzyme inherited on the X chromosome. Affected males may have progressive extrapyramidal disease, myopathy, seizures, and variable mental retardation in conjunction with hemolytic anemia. Nine Japanese patients had neural or myopathic symptoms with hemolysis; 6 had hemolysis alone; 7 had neural or myopathic symptoms alone; and 1 had no symptoms. The gene for PGK is particularly large, spanning 23 kb, and various genetic abnormalities, including nucleotide substitutions, gene deletions, missense, and splicing mutations, result in PGK deficiency.

**DEFICIENCIES OF ENZYMES OF THE HEXOSE MONOPHOSPHATE PATHWAY**

The most important function of the hexose monophosphate pathway is to maintain glutathione (GSH) in its reduced state as protection against oxidant threats from certain drugs and compounds, such as hydrogen peroxide, that are generated within RBCs. If glutathione, or any compound or enzyme necessary for maintaining it in the reduced state, is decreased, the SH groups of the RBC membrane are oxidized and the hemoglobin becomes denatured and may aggregate in the reduced state, is decreased, the SH groups of the RBC membrane are oxidized and the hemoglobin becomes denatured and may aggregate. Glutathione is essential for the physiologic inactivation of oxidant compounds, such as hydrogen peroxide, that are generated within RBCs. If glutathione, or any compound or enzyme necessary for maintaining it in the reduced state, is decreased, the SH groups of the RBC membrane are oxidized and the hemoglobin becomes denatured and may aggregate.

**EPISODIC OR INDUCED HEMOLYTIC ANEMIA**

**Etiology**

G6PD catalyzes the conversion of glucose 6-phosphate to 6-phosphogluconic acid. This reaction produces NADPH, which maintains GSH in the reduced, functional state (see Fig. 463-1). Reduced GSH provides protection against oxidant threats from certain drugs and infections that would otherwise cause precipitation of hemoglobin (Heinz bodies) or damage the RBC membrane.

Synthesis of RBC G6PD is determined by a gene on the X chromosome. Thus, heterozygous females have intermediate enzymatic activity and have 2 populations of RBCs: one is normal, and the other is deficient in G6PD activity. Because they have fewer susceptible cells, most heterozygous females do not have evident clinical hemolysis after exposure to oxidant drugs. Rarely, the majority of RBCs is G6PD deficient in heterozygous females because the inactivation of the normal X chromosome is random and sometimes exaggerated (Lyon-Beutler hypothesis).

Disease involving this enzyme therefore occurs more frequently in males than in females. Approximately 13% of male Americans of African descent have a mutant enzyme (G6PD A−) that results in a deficiency of RBC G6PD activity (5-15% of normal). Italians, Greeks, and other Mediterranean, Middle Eastern, African, and Asian ethnic groups also have a high incidence, ranging from 5% to 40%, of a variant designated G6PD B− (G6PD Mediterranean). In these variants, the G6PD activity of homozygous females or hemizygous males is <5% of normal. Therefore, the defect in Americans of African descent is less severe than that in Americans of European descent. A third mutant enzyme with markedly reduced activity (G6PD Canton) occurs in approximately 5% of the Chinese population.

463.3 Glucose-6-Phosphate Dehydrogenase Deficiency and Related Deficiencies

George B. Segel and Lisa R. Hackney

Glucose-6-phosphate dehydrogenase (G6PD) deficiency, the most frequent disease involving enzymes of the hexose monophosphate pathway, is responsible for 2 clinical syndromes, episodic hemolytic anemia and chronic nonspherocytic hemolytic anemia. The most common manifestations of this disorder are neonatal jaundice and episodic acute hemolytic anemia, which is induced by infections, certain drugs, and, rarely, fava beans. This X-linked deficiency affects more than 400 million people worldwide, representing an overall 4.9% global prevalence. The global distribution of this disorder parallels that of malaria, representing an example of "balanced polymorphism," in which there is an evolutionary advantage of resistance to falciparum malaria in heterozygous females that outweighs the small negative effect of affected hemizygous males.

The deficiency is caused by inheritance of any of a large number of abnormal alleles of the gene responsible for the synthesis of the G6PD protein. About 140 mutations have been described in the gene responsible for the synthesis of the G6PD protein. Many of these mutations are single base changes leading to amino acid substitutions and destabilization of the G6PD enzyme. A web-accessible database catalogs G6PD mutations (http://www.bioinf.org.uk/g6pd). Figure 463-2 shows some of the mutations that cause episodic versus chronic hemolysis. Milder disease is associated with mutations near the amino terminus of the G6PD molecule, and chronic nonspherocytic hemolytic anemia is associated with mutations clustered near the carboxyl terminus. The normal enzyme found in most populations is designated G6PD B+. A normal variant, designated G6PD A+, is common in Americans of African descent.

**Figure 463-2 Most common mutations along coding sequence of G6PD gene. Exons are shown as open numbered boxes. Open circles are mutations causing classes II and III variants. Filled circles represent sporadic mutations giving rise to severe variants (class I). Open ellipses are mutations causing class IV variants. X a nonsense mutation; f, a splice site mutation; filled square, small deletion. 202A and 968C are the two sites of base substitution in G6PD-A. (From Cappellini MD, Fiorelli G: Glucose-6-phosphate dehydrogenase deficiency, Lancet 371:64–74, 2008.)**
Unstained or supravital preparations of RBCs reveal precipitated globin may appear in the plasma and subsequently in the urine. Binding proteins, such as haptoglobin, are saturated, and free hemoglobin may occur. The onset of acute hemolysis usually results in a precipitous fall in hemoglobin, known as Heinz bodies. The RBC inclusions are not visible on the Wright-stained blood film. Cells that contain these inclusions are seen only within the first 3–4 days of illness because they are rapidly cleared from the blood. Also, the blood film may contain red cells with what appears to be a bite taken from their periphery and polychromasia (evidence of bluish, larger RBCs), representing reticulocytosis (Fig. 463-3).

**Clinical Manifestations**

Most individuals with G6PD deficiency are asymptomatic, with no clinical manifestations of illness unless triggered by infection, drugs, or ingestion of fava beans. Typically, hemolysis ensues in about 24–48 hr after a patient has ingested a substance with oxidant properties. In severe cases, hemoglobinuria and jaundice result, and the hemoglobin concentration may fall precipitously. Drugs that elicit hemolysis in these individuals include aspirin, sulfonamides, rasburicase, and antimalarials, such as primaquine (Table 463-1). The degree of hemolysis varies with the inciting agent, amount ingested, and severity of the enzyme deficiency. In some individuals, ingestion of fava beans also produces an acute, severe hemolytic syndrome, known as favism. Fava beans contain divicine, isouramil, and convicine, which ultimately lead to the production of hydrogen peroxide and other reactive oxygen products. Favism is thought to be more frequently associated with the G6PD B– variant. In the G6PD A– variant, the stability of the folded protein dimer is impaired, and this defect is accentuated as the RBCs age. Thus, hemolysis decreases as older red cells are destroyed, even if administration of the drug is continued. This recovery results from the age-labile enzyme, which is abundant and more stable in younger RBCs. The associated reticulocytosis produces a compensated hemolytic process in which the blood hemoglobin may be only slightly decreased, despite continued exposure to the offending agent.

In G6PD A– variant, spontaneous hemolysis and hyperbilirubinemia have been observed in preterm infants. In newborns with the G6PD B– and G6PD Canton varieties, hyperbilirubinemia and even kernicterus may occur. Neonates with coinheritance of G6PD deficiency and a mutation of the promoter of uridine-diphosphate-glucuronyl transferase (UGT1A1), seen in Gilbert syndrome, have more severe neonatal jaundice. When a pregnant woman ingests oxidant drugs, they may be transmitted to her G6PD-deficient fetus, and hemolytic anemia and jaundice may be apparent at birth.

**Laboratory Findings**

The onset of acute hemolysis usually results in a precipitous fall in hemoglobin and hematocrit. If the episode is severe, the hemoglobin binding proteins, such as haptoglobin, are saturated, and free hemoglobin may appear in the plasma and subsequently in the urine. Unstained or supravital preparations of RBCs reveal precipitated hemoglobin, known as Heinz bodies. The RBC inclusions are not visible on the Wright-stained blood film. Cells that contain these inclusions are seen only within the first 3–4 days of illness because they are rapidly cleared from the blood. Also, the blood film may contain red cells with what appears to be a bite taken from their periphery and polychromasia (evidence of bluish, larger RBCs), representing reticulocytosis (Fig. 463-3).

**Figure 463-3** Morphologic erythrocyte changes (anisopoikilocytosis, bite cells) during acute hemolysis in a G6PD-deficient patient. Arrows show bite cells. Anisopoikilocytosis is abnormality in the shape or size of erythrocytes. (From Cappellini MD, Fiorelli G: Glucose-6-phosphate dehydrogenase deficiency, Lancet 371:64–74, 2008.)

**Diagnosis**

The diagnosis depends on direct or indirect demonstration of reduced G6PD activity in RBCs. By direct measurement, enzyme activity in affected persons is ≤10% of normal, and the reduction of enzyme activity is more extreme in Americans of European descent and in Asians than in Americans of African descent. Satisfactory screening tests are based on decoloration of methylene blue, reduction of methemoglobin, or fluorescence of NADPH. Immediately after a hemolytic episode, reticulocytes and young RBCs predominate. These young cells have significantly higher enzyme activity than do older cells in the A– variety (African). Testing may therefore have to be deferred for a few weeks before a diagnostically low level of enzyme can be shown. The diagnosis can be suspected when G6PD activity is within the low-normal range in the presence of a high reticulocyte count. G6PD variants also can be detected by electrophoretic and molecular analysis. G6PD deficiency should be considered in any neonatal patients with hyperbilirubinemia and borderline low G6PD activity.

**Prevention and Treatment**

Prevention of hemolysis constitutes the most important therapeutic measure. When possible, males belonging to ethnic groups with a significant incidence of G6PD deficiency (e.g., Greeks, southern Italians, Sephardic Jews, Filipinos, southern Chinese, Americans of African descent, and Thais) should be tested for the defect before known oxidant drugs are given. The usual doses of aspirin and trimethoprim-sulfamethoxazole do not cause clinically relevant hemolysis in the A– variety. Aspirin administered in doses used for acute rheumatic fever (60–100 mg/kg/24 hr) may produce a severe hemolytic episode. Infants with severe neonatal jaundice who belong to these ethnic groups also require testing for G6PD deficiency because of their heightened risk for this defect. If severe hemolysis has occurred,
supportive therapy may require blood transfusions, although recovery is the rule when the oxidant agent is discontinued.

**CHRONIC HEMOLYTIC ANEMIAS ASSOCIATED WITH DEFICIENCY OF G6PD OR RELATED FACTORS**

Chronic nonspherocytic hemolytic anemia has been associated with profound deficiency of G6PD caused by enzyme variants, particularly those defective in quantity, activity, or stability. The gene defects leading to chronic hemolysis are located primarily in the region of the NADP binding site near the carboxyl terminus of the protein (see Fig. 463-2). These include the Loma Linda, Tomah, Iowa, Beverly Hills, Nashville, Riverside, Santiago de Cuba, and Andalus variants. Persons with G6PD B−enzyme deficiency occasionally have chronic hemolysis, and the hemolytic process may worsen after ingestion of oxidant drugs. Splenectomy is of little value in these types of chronic hemolysis.

Other enzyme defects may impair the regeneration of GSH as an oxidant “sump” (see Fig. 463-1). Mild, chronic nonspherocytic anemia has been reported in association with decreased RBC GSH, resulting from γ-glutamylcysteine or GSH synthetase deficiencies. Deficiency of 6-phosphogluconate dehydrogenase has been associated primarily with drug-induced hemolysis, and hemolysis with hyperbilirubinemia has been related to a deficiency of GSH peroxidase in newborn infants.

AUTOIMMUNE HEMOLYTIC ANEMIAS

A number of extrinsic agents and disorders may lead to premature destruction of red blood cells (RBCs). Among the most clearly defined are antibodies associated with immune hemolytic anemias. The hallmark of this group of diseases is the positive result of the direct antiglobulin (Coombs) test, which detects a coating of immunoglobulin or components of complement on the RBC surface. The most important immune hemolytic disorder in pediatric practice is hemolytic disease of the newborn (erythroblastosis fetalis), caused by transplacental transfer of maternal antibody active against the RBCs of the fetus, that is, isoimmune hemolytic anemia (see Chapter 103.2). Various other immune hemolytic anemias are autoimmune (Table 464-1) and may be idiopathic or related to various infections (Epstein-Barr virus, and rarely HIV, cytomegalovirus, and mycoplasma), immunologic diseases (systemic lupus erythematosus [SLE], rheumatoid arthritis), immunodeficiency diseases (agammaglobulinemia), autoimmune lymphoproliferative disorder, dysgamaglobulinemias), neoplasms (lymphoma, leukemia, and Hodgkin disease), or drugs (methylxypin, l-dopa). Other drugs (penicillin, cephalosporins) cause hemolysis by means of "drug-dependent antibodies"—that is antibodies directed toward the drug and in some cases toward an RBC membrane antigen as well.

AUTOIMMUNE HEMOLYTIC ANEMIAS ASSOCIATED WITH "WARM" ANTIBODIES

Etiology

In the autoimmune hemolytic anemias, autoantibodies are directed against RBC membrane antigens, but the pathogenesis of antibody induction is uncertain. The autoantibody may be produced as an inappropriate immune response to an RBC antigen or to another antigenic epitope similar to an RBC antigen, known as molecular mimicry. Alternatively, an infectious agent may alter the RBC membrane so that it becomes "foreign" or antigenic to the host. The antibodies usually react to epitopes (antigens) that are "public" or common to all human RBCs, such as Rh proteins.

In most instances of warm antibody hemolysis, no underlying cause can be found; this is the primary or idiopathic type (see Table 464-1). If the autoimmune hemolysis is associated with an underlying disease, such as a lymphoproliferative disorder, SLE, Evans syndrome, or immunodeficiency, it is secondary. In as many as 20% of cases of immune hemolysis, drugs may be implicated (Table 464-2).

Drugs (penicillin or sometimes cephalosporins) that cause hemolysis via the "hapten" mechanism (immune but not autoimmune) bind tightly to the RBC membrane (see Table 464-1). Antibodies to the drug, either newly or previously formed, bind to the drug molecules on RBCs, mediating their destruction in the spleen. In other cases, certain drugs, such as quinine and quinidine, do not bind to RBCs but, rather, form part of a "ternary complex," consisting of the drug, an RBC membrane antigen, and an antibody that recognizes both (see Table 464-1). Methylxypin and sometimes cephalosporins may, by unknown mechanisms, incite true autoantibodies to RBC membrane antigens, so that the presence of the drug is not required to cause hemolysis. Cephalosporins are the most common cause of drug-immune hemolytic anemia.

Clinical Manifestations

Autoimmune hemolytic anemias may occur in either of 2 general clinical patterns. The first, an acute transient type lasting 3-6 mo and occurring predominantly in children ages 2-12 yr, accounts for 70-80% of patients. It is frequently preceded by an infection, usually respiratory.
Onset may be acute, with prostration, pallor, jaundice, fever, and hemoglobinuria, or more gradual, with primarily fatigue and pallor. The spleen is usually enlarged and is the primary site of destruction of immunoglobulin (Ig) G–coated RBCs. Underlying systemic disorders are unusual. A consistent response to glucocorticoid therapy, a low mortality rate, and full recovery are characteristic of the acute form. The other clinical pattern involves a prolonged and chronic course, which is more frequent in infants and in children >12 yr old. Hemolysis may continue for many months or years. Abnormalities involving other blood elements are common, and the response to glucocorticoids is variable and inconsistent. The mortality rate is approximately 10%, and death is often attributable to an underlying systemic disease.

### Laboratory Findings
In many cases, anemia is profound, with hemoglobin levels <6 g/dL. Considerable spherocytosis and polychromasia (reflecting the reticulocyte response) are present. More than 50% of the circulating RBCs may be reticulocytes, and nucleated RBCs usually are present. In some cases, a low reticulocyte count may be found, particularly early in the episode. Leukocytosis is common. The platelet count is usually normal, but concomitant immune thrombocytopenic purpura sometimes occurs (Evans syndrome). The prognosis for patients with Evans syndrome is guarded, because many have or eventually have a chronic disease, including SLE, an immune deficiency syndrome, or the autoimmune lymphoproliferative syndrome.

Results of the direct antiglobulin test are strongly positive, and free antibody can sometimes be demonstrated in the serum (indirect Coombs test). These antibodies are active at 35-40°C (95-104°F) (“warm” antibodies) and most often belong to the IgG class. They do not require complement for activity and are usually incomplete antibodies that do not produce agglutination in vitro. Antibodies from the serum and those eluted from the RBCs react with the RBCs of many persons in addition to those of the patient. They often have been regarded as nonspecific panagglutinins, but careful studies have revealed specificity for RBC antigens of the Rh system in 70% of patients (~50% of adult patients). Complement, particularly fragments of C3b, may be detected on the RBCs in conjunction with IgG. The Coombs test result is rarely negative because of the limited sensitivity of the Coombs reaction. A minimum of 260–400 molecules of IgG per cell is necessary on the RBC membrane to produce a positive reaction. Special tests are required to detect the antibody in cases of “Coombs-negative” autoimmune hemolytic anemia. In warm antibody hemolytic anemia, the direct Coombs test may detect IgG alone, both IgG– and complement fragments, or solely complement fragments if the level of RBC-bound IgG is below the detection limit of the anti-IgG Coombs reagent.

### Treatment
Transfusions may provide only transient benefit but may be lifesaving in cases of severe anemia by providing delivery of oxygen until the effect of other treatment is observed. All tested units for transfusion are serologically incompatible. It is important to identify the patient’s ABO blood group to avoid a hemolytic transfusion reaction mediated by anti-A or anti-B. The blood bank should also test for the presence of an underlying alloantibody, which could cause rapid hemolysis of transfused red cells. Patients who have neither been previously transfused nor pregnant are unlikely to harbor an alloantibody. Early consultation between the clinician and the blood bank physician is essential. Failure to transfuse a profoundly anemic infant or child may lead to serious morbidity and even death.

Patients with mild disease and compensated hemolysis may not require any treatment. If the hemolysis is severe and results in significant anemia or symptoms, treatment with glucocorticoids is initiated. Glucocorticoids decrease the rate of hemolysis by blocking macrophage function by downregulating Fcγ receptor expression, decreasing the production of the autoantibody, and perhaps enhancing the elution of antibody from the RBCs. Prednisone or its equivalent is administered at a dose of 2 mg/kg/24 hr. In some patients with severe hemolysis, doses of prednisone of up to 6 mg/kg/24 hr may be required to reduce the rate of hemolysis. Treatment should be continued until the rate of hemolysis decreases, and then the dose gradually reduced. If relapse occurs, resumption of the full dosage may be necessary. The disease tends to remit spontaneously within a few weeks or months. The Coombs test result may remain positive even after the hemoglobin level returns to normal. It is usually safe to discontinue prednisone once the direct Coombs test result becomes negative. When hemolytic anemia remains severe despite glucocorticoid therapy, or if very large doses are necessary to maintain a reasonable hemoglobin level, IV immunoglobulin may be tried. Rituximab, a monoclonal antibody that targets B lymphocytes, the source of antibody production, is useful in chronic cases refractory to conventional therapy. Plasmapheresis has been used in refractory cases but generally is not helpful. Splenectomy may be beneficial but is complicated by a heightened risk of infection with encapsulated organisms, particularly in patients <6 yr. Prophylaxis with appropriate vaccines (pneumococcal, meningococcal, and Haemophilus influenzae type b) before splenectomy and with oral penicillin after splenectomy are indicated.

### Course and Prognosis
Acute idiopathic autoimmune hemolytic disease in childhood varies in severity but is self-limited; death from untreated anemia is rare. Approximately 30% of patients have chronic hemolysis, often associated with an underlying disease, such as SLE, lymphoma, or leukemia.
The presence of antiphospholipid antibodies in adult patients with immune hemolysis predisposes to thrombosis. Mortality in chronic cases depends on the primary disorder.

**AUTOIMMUNE HEMOLYTIC ANEMIAS ASSOCIATED WITH “COLD” ANTIBODIES**

“Cold” antibodies agglutinate RBCs at temperatures <37°C (98.6°F). They are primarily of the IgM class and require complement for hemolytic activity. The highest temperature at which RBC agglutination occurs is called the thermal amplitude. A higher thermal amplitude antibody—that is, one that can bind to RBCs at temperatures achievable in the body—results in hemolysis with exposure to a cold environment. High antibody titers are associated with a high thermal amplitude.

**Cold Agglutinin Disease**

Cold antibodies usually have specificity for the oligosaccharide antigens of the I/i system. They may occur in primary or idiopathic cold agglutinin disease, secondary to infections such as those from *Mycoplasma pneumoniae* and Epstein-Barr virus, or secondary to lymphoproliferative disorders. After *M. pneumoniae* infection, the anti-I levels may increase considerably, and occasionally, enormous increases may occur to titers ≥1/30,000. The antibody has specificity for the I antigen and thus reacts poorly with human cord RBCs, which possess the i antigen but exhibit low levels of I. Patients with infectious mononucleosis occasionally have cold agglutinin disease, and the antibodies in these patients often have anti-i specificity. This antibody causes less hemolysis in adults than in children because adults have fewer i molecules on their RBCs. Spontaneous RBC agglutination is observed in the cold and in vitro, and RBC aggregates are seen on the blood film. Mean corpuscular volume may be spuriously elevated because of RBC agglutination. The severity of the hemolysis is related to the thermal amplitude of the antibody, which itself partly depends on the IgM antibody titer.

When very high titers of cold antibodies are present and active near body temperature, severe intravascular hemolysis with hemoglobinemia and hemoglobinuria may occur and may be heightened on a patient’s exposure to cold (external temperature or ingested foods). Each IgM molecule has the potential to activate a C1 molecule so that large amounts of complement are found on the RBCs in cold agglutinin disease. These sensitized RBCs may undergo intravascular complement-mediated lysis or may be destroyed in the liver and spleen. Only complement, not IgM, is detected on RBCs because the IgM is removed during the washing steps of the direct antiglobulin test.

Cold agglutinin disease is less common in children than in adults and more frequently results in an acute, self-limited episode of hemolysis. Glucocorticoids are much less effective in cold agglutinin disease than in disease with warm antibodies. Patients should avoid exposure to cold and should be treated for underlying disease. In the uncommon patients with severe hemolytic disease, treatment includes immunosuppression and plasmapheresis. Successful treatment of cold agglutinin disease has been reported with the monoclonal antibody rituximab, which effectively depletes B lymphocytes. Splenectomy is not useful in cold agglutinin disease.

**Paroxysmal Cold Hemoglobinuria**

Paroxysmal cold hemoglobinuria is mediated by the Donath-Landsteiner (D-L) hemolysin, which is an IgG cold-reactive autoantibody with anti-P specificity. In vitro, the D-L antibody binds to RBCs in the cold and the RBCs are lysed by complement as the temperature is increased to 37 degrees C. A similar sequence is thought to occur in vivo as RBCs move from the cooler extremities to warmer parts of the circulation. Most reported cases are self-limited; many patients experience only one paroxysm of hemolysis. Congenital or acquired syphilis used to be the most common underlying cause of paroxysmal cold hemoglobinuria, but today, most cases are associated with nonspecific viral infections. This disorder accounts for 30% of immune hemolytic episodes among children. Treatment includes transfusion for severe anemia and avoidance of cold ambient temperatures.

Chapter 465
Hemolytic Anemias Secondary to Other Extracellular Factors
George B. Segel

FRAGMENTATION HEMOLYSIS
(See Table 457-1 in Chapter 457.)
Red blood cell (RBC) destruction may occur in hemolytic anemias because of mechanical injury as the cells traverse a damaged vascular bed. Damage may be microvascular when RBCs are sheared by fibrin in the capillaries during intravascular coagulation or when renovascular disease accompanies the hemolytic-uremic syndrome (HUS) (see Chapter 518) or thrombotic thrombocytopenic purpura (see Chapter 484.5). Larger vessels may be involved in Kasabach-Merritt syndrome (giant hemangiomia and thrombocytopenia; see Chapter 505) or when a replacement heart valve is poorly epithelialized. The blood film shows many “schistocytes,” or fragmented cells, as well as polychromatophilia, reflecting the reticulocytosis (see Fig. 458-4F in Chapter 458). Secondary iron deficiency may complicate the intravascular hemolysis because of urinary hemoglobin and hemosiderin iron loss (see Fig. 457-2 in Chapter 457). Treatment should be directed toward the underlying condition, and the prognosis depends on the effectiveness of this treatment. The benefit of transfusion may be transient because the transfused cells are destroyed as quickly as those produced by the patient.

It is critical to determine the precise etiology of the fragmentation hemolysis because the treatment depends on the underlying problem (Table 465-1). Thrombotic thrombocytopenic purpura results from an antibody to an enzyme (AdamTS13) that regulates the size of von Willebrand multimers. The lack of this enzyme results in a marked increase in multimer size and a resultant thrombotic microangiopathy. The treatment involves plasmapheresis (PLEX) to remove the antibody and replace the AdamTS13. In contrast, HUS results from Shiga toxin produced by Escherichia coli 0157 and may not be helped by PLEX. Atypical HUS involves activation of the alternative complement pathway and is currently treated with eculizumab (anti C5), an inhibitor of the complement pathway. PLEX may reduce the RBC fragmentation and improve the platelet count but has little effect on the tissue (kidney) vasculopathy and thus is not usually recommended. Pneumococcal-induced HUS results from neuraminidase produced by the bacteria, which damages the membranes of the RBCs and the kidney, exposing the T-antigen. Plasma contains natural antibody to the T-antigen producing hemolysis, renal damage, and a thrombotic microangiopathy.

THERMAL INJURY
Extensive burns may directly damage the RBCs and cause hemolysis that results in the formation of spherocytes. Blood loss and marrow suppression may contribute to anemia and require blood transfusion. Erythropoietin (EPO) has been used as treatment for diminished RBC production.

RENAL DISEASE
The anemia of uremia is multifactorial in origin. EPO production may be decreased and the marrow suppressed by toxic metabolites. Furthermore, the RBC life span often is shortened owing to retention of
metabolites and organic acidemia. The use of EPO in chronic renal disease has markedly decreased the need for blood transfusion.

**LIVER DISEASE**

A change in the ratio of cholesterol to phospholipids in the plasma may result in changes in the composition of the RBC membrane and shortening of the RBC life span. Some patients with liver disease have many target RBCs on the blood film, whereas others have a preponderance of spiculated cells. These morphologic changes reflect the alterations in the plasma lipid composition.

**TOXINS AND VENOMS**

Bacterial sepsis caused by *Haemophilus influenzae*, staphylococci, or streptococci may be complicated by accompanying hemolysis. Particularly severe hemolytic anemia has been observed in clostridial infections and results from a hemolytic clostridial toxin. Large numbers of spherocytes may be seen on the blood film. Spherocytic hemolysis also may be noted after bites by various snakes, including cobras, vipers, and rattlesnakes, which have phospholipases in their venom. Large numbers of bites by insects, such as bees, wasps, and yellow jackets, also may cause spherocytic hemolysis by a similar mechanism (see Chapter 725).

**WILSON DISEASE**

(See Chapter 357.2.)

An acute and self-limited episode of hemolytic anemia may precede by years the onset of hepatic or neurologic symptoms in Wilson disease. This event appears to result from the toxic effects of free copper on the RBC membrane. The blood film often (but not always) shows large numbers of spherocytes, and the Coombs test result is negative. Because early diagnosis of Wilson disease permits prophylactic treatment with penicillamine and prevention of hepatic and neurologic disease, correct assessment of this rare type of hemolysis is important.

*Bibliography is available at Expert Consult.*
Bibliography
Polycythemia exists when the red blood cell (RBC) count, hemoglobin level, and total RBC volume all exceed the upper limits of normal. In postpubertal individuals, an RBC mass >25% above the mean normal value (based on body surface area) or a hemoglobin >18.5 g/dL (in males) or >16.5 g/dL (in females) indicate absolute erythrocytosis. A decrease in plasma volume, such as occurs in acute dehydration and burns, may result in a high hemoglobin value. These situations are more accurately designated as hemoconcentration or relative polycythemia because the RBC mass is not increased and normalization of the plasma volume restores hemoglobin to normal levels. Once the diagnosis of true polycythemia is made, sequential studies should be done to determine the underlying etiology (Fig. 466-1).

**CLONAL (PRIMARY) POLYCYTHEMIA (POLYCYTHEMIA RUBRA VERA)**

**Pathogenesis**

Polycythemia vera is an acquired clonal myeloproliferative disorder. Although primarily manifesting as erythrocytosis, thrombocytosis and leukocytosis can also be seen. When isolated severe thrombocytosis exists in the absence of erythrocytosis, the myeloproliferative disorder is called essential thrombocytopenia. Polycythemia vera is rare in children. A gain-of-function mutation of JAK2, a cytoplasmic tyrosine kinase, is found in more than 90% of adult patients with polycythemia vera, but in <30% of children with this condition. The erythropoietin

Non-Clonal Polycythemia
Amanda M. Brandow and Bruce M. Camitta

PATHOGENESIS
Nonclonal polycythemia is diagnosed when polycythemia is caused by a physiologic process that is not derived from a single cell (Table 467-1). Nonclonal polycythemia can be congenital or acquired (secondary).

Congenital Polycythemia
Lifelong or familial polycythemia should trigger a search for a congenital problem. These inherited conditions may be transmitted as dominant or recessive disorders. Autosomal dominant causes include hemoglobins that have increased oxygen affinity ($P_{50}$ [partial pressure of oxygen in the blood at which the hemoglobin is 50% saturated]) <20 mm Hg), erythropoietin receptor mutations resulting in an enhanced effect of erythropoietin or mutations in the von Hippel–Lindau gene that result in altered intracellular oxygen sensing. Another rare cause is autosomal recessive 2,3-diphosphoglyceric acid deficiency, which leads to a left shift of the oxygen dissociation curve, increased oxygen affinity, and consequent polycythemia.

</table>

Subtle decreases in oxygen delivery to tissues may cause polycythemia. Congenital methemoglobinemia resulting from an autosomal recessive deficiency of cytochrome b5 reductase may cause cyanosis and polycythemia (see Chapter 462.7). Most affected individuals are asymptomatic. Neurologic abnormalities may be present in patients whose enzyme deficits are not limited to hematopoietic cells. Hemoglobin M disease (autosomal dominant) causes methemoglobinemia and can lead to polycythemia. Cyanosis may occur in the presence of as little as 1.5 g/dL of methemoglobin but is uncommon in other hemoglobin variants unless hyperviscosity results in localized hypoxemia.

Acquired Polycythemia

Polycythemia may be present in clinical situations associated with chronic arterial oxygen desaturation. Cardiovascular defects involving right-to-left shunts and pulmonary diseases interfering with proper oxygenation are the most common causes of hypoxic polycythemia. Clinical findings usually include cyanosis, hyperemia of the sclerae and mucous membranes, and clubbing of the fingers. As the hematocrit rises to >65%, clinical manifestations of hyperviscosity, such as headache and hypertension, may require phlebotomy. Living at high altitudes also causes hypoxic polycythemia; the hemoglobin level increases approximately 4% for each rise of 1,000 m in altitude. Partial obstruction of a renal artery rarely results in polycythemia. Polycythemia has also been associated with benign and malignant tumors that secrete erythropoietin. Exogenous or endogenous excess of anabolic steroids also may cause polycythemia. A common spurious cause is a decrease in plasma volume such as in moderate to severe dehydration.

DIAGNOSIS

Figure 466-1 outlines sequential studies to evaluate polycythemia.

TREATMENT

For mild disease, observation is sufficient. When the hematocrit is >65-70% (hemoglobin >23 g/dL), blood viscosity markedly increases. Periodic phlebotomy may prevent or decrease symptoms such as headache, dizziness, or exertional dyspnea. Apherased blood should be replaced with plasma or saline to prevent hypovolemia in patients accustomed to a chronically elevated total blood volume. Increased demand for red blood cell production may cause iron deficiency. Iron-deficient microcytic red cells are more rigid, further increasing the risk of intracranial and other thromboses in patients with polycythemia. Periodic assessment of iron status, with treatment of iron deficiency, should be performed.

Bibliography is available at Expert Consult.
Bibliography

Pancytopenia refers to a reduction below normal values of all 3 peripheral blood lineages: leukocytes, platelets, and erythrocytes. Pancytopenia requires microscopic examination of a bone marrow biopsy specimen and a marrow aspirate to assess overall cellularity and morphology. There are 3 general categories of pancytopenia depending on the marrow findings.

**Hypocellular marrow** on biopsy is seen with inherited (“constitutional”) marrow failure syndromes, acquired aplastic anemia of varied etiologies (see Chapter 469), the hypoplastic variant of myelodysplastic syndrome (MDS), and some cases of paroxysmal nocturnal hemoglobinuria with pancytopenia.

**Cellular marrow** is seen (a) with primary bone marrow disease, such as acute leukemia (see Chapter 494), and MDS, and (b) secondary to systemic disease, such as autoimmune disorders (systemic lupus erythematosus; Chapter 158), vitamin B₁₂ or folate deficiency (see Chapters 49.6 and 49.7), storage disease (Gaucher and Niemann-Pick diseases; see Chapter 86.4), overwhelming infection, sarcoidosis, and hypersplenism.

**Bone marrow infiltration** can cause pancytopenia in metastatic solid tumors, myelofibrosis, hemophagocytic lymphohistiocytosis (see Chapter 507) and osteopetrosis (see Chapter 699).

Inherited (“constitutional”) pancytopenia is defined as a decrease in marrow production of the 3 major hematopoietic lineages that occurs on an inherited basis, resulting in anemia, neutropenia, and thrombocytopenia. Any of these conditions (Tables 468-1 and 468-2) can be transmitted as a simple mendelian disorder by mutant genes with inherited patterns of autosomal dominant, autosomal recessive, or X-linked types. Modifying genes and acquired factors may also be operative. Inherited pancytopenias account for approximately 30% of cases of pediatric marrow failure. Fanconi anemia is the most common of these disorders.
**FANCONI ANEMIA**

**Etiology and Epidemiology**

Fanconi anemia (FA) is primarily inherited in an autosomal recessive manner (one uncommon form is X-linked recessive). It occurs in all racial and ethnic groups. At presentation, patients with FA may have: (1) typical physical anomalies and abnormal hematologic findings (majority of the patients); (2) normal physical features but abnormal hematologic findings (about one-third of patients); or (3) physical anomalies and normal hematologic findings (unknown percentage). There can be sibling discordance in clinical and hematologic findings, even in affected monozygotic twins. Approximately 75% of patients are 3-14 yr of age at the time of diagnosis.

**Pathology**

Patients have abnormal chromosome fragility, which is seen in metaphase preparations of peripheral blood lymphocytes cultured with phytohemagglutinin and enhanced by adding clastogenic agents such as diepoxybutane (DEB) and mitomycin C. Cell fusion of FA cells with normal cells or with cells from some unrelated patients with FA produces a corrective effect on chromosomal fragility, a process called *complementation*. This phenomenon allows subtyping of cases of FA into discrete complementation groups. Fifteen different complementation groups have been identified with different FA (FANC) genes that are mutated in each of them: A, B, C, D1/BRCA2, D2, E, F, G, I, J, L, M, N, O, P). An additional 2 genes, XRCC2 and ECCR4, have been published and need further studies. After their discovery, the genes are prefixed with FANC (FANCA, FANCB, and so on). FANCD1 is identical to the breast cancer susceptibility gene, BRCA2. The protein products of wild-type FANC genes are involved in the DNA damage recognition and repair biochemical pathways. Therefore, mutant gene proteins lead to genomic instability and chromosome fragility. An inability of FA cells to remove oxygen-free radicals, resulting in oxidative damage, is an additional mechanism that may contribute to the disease pathogenesis. Leukocyte telomere length is significantly shortened but telomerase activity is increased, suggesting a high proliferative rate of marrow progenitors that ultimately leads to their premature senescence. Increased marrow cell apoptosis occurs and is

mediated by Fas, a membrane glycoprotein receptor containing an integral death domain. A consistent finding is diminished cellular interleukin-6 production along with markedly heightened tumor necrosis factor-α generation.

Clinical Manifestations

The most common anomaly in FA is hyperpigmentation of the trunk, neck, and intertriginous areas, as well as café-au-lait spots and vitiligo, alone or in combination (Fig. 468-1 and Table 468-3). Half the patients have short stature. In some patients, growth failure is aggravated by abnormal growth hormone secretion or with hypothyroidism. Absence of radii and thumbs that are hypoplastic, supernumerary, bifid, or absent are common. The “r” radial pulse may be weak or absent. Anomalies of the feet, congenital hip dislocation, and leg abnormalities are seen. A male patient with FA may have an underdeveloped penis; undescended, atrophic, or absence of the testes; and hypospadias or phimosis. Females can have malformations of the vagina, uterus, and ovary. Many patients have a FA “facies,” including microcephaly, small eyes, epicanthal folds, and abnormal shape, size, or positioning of the ears (Fig. 468-1). Ectopic, pelvic, or horseshoe kidneys are detected by imaging and may show other organs as duplicated, hypoplastic, dysplastic, or absent kidneys. Cardiovascular and gastrointestinal malformations also occur. Approximately 10% of patients with FA are cognitively delayed.

Figure 468-1  A 3 yr old boy with Fanconi anemia who exhibits several classic phenotype features. A, Front view. B, Face. C, Hands. D, Back right shoulder. The features to be noted include short stature, dislocated hips, microcephaly, a broad nasal base, epicanthal folds, micrognathia, thumbs attached by a thread, and café-au-lait spots with hypopigmented areas beneath. (From Nathan DC, Orkin SH, Ginsburg D, et al, editors: Nathan and Oski’s hematology of infancy and childhood, ed 6, vol I, Philadelphia, 2003, WB Saunders, p. 285.)
Laboratory Findings
Marrow failure usually ensues in the 1st decade of life. Thrombocytopenia and red blood cell macrocytosis often appears initially, with subsequent onset of granulocytopenia and then anemia. Severe aplasia develops in most cases, but its full expression is variable and evolves over a period of months to years. The marrow becomes progressively hypocellular and fatty, like that in severe acquired aplastic anemia. Chromosome fragility is indicated by spontaneously occurring chromatid breaks, rearrangements, gaps, endoreduplications, and chromatid exchanges in blood lymphocytes cultured with phytohemagglutinin as well as in cultured skin fibroblasts, underscoring the constitutional nature of the disorder. With addition of DEB or mitomycin C, fragility is strikingly enhanced in lymphocyte cultures of patients with FA in comparison with those of controls. For prenatal diagnosis, abnormal chromosome breakage analysis and genetic testing can be performed in amniotic fluid cells or in tissue from a chorionic villus biopsy.

Complications
In addition to the low blood counts and physical anomalies, a major feature of the phenotype of FA is the propensity for cancer. The most frequent solid tumors are squamous cell carcinomas of the head, neck, and upper esophagus, followed by carcinomas of the vulva and/or anus, cervix, and lower esophagus. Human papilloma virus is suspected in the pathogenesis. Some patients experience oral cancer after bone marrow transplantation; it is unclear whether this treatment has an effect on the incidence. Benign and malignant liver tumors occur (adenomas, hepatomas) are usually associated with androgen therapy for aplastic anemia. Androgens are also implicated in the etiology of peliosis hepatitis (blood-filled hepatic sinusoids). Peliosis hepatitis is reversible when androgen therapy is discontinued, and tumors may regress. Clonal marrow cytogenetic abnormalities are common in FA, and at follow-up can either be stable, intermittently detected, or progressive and develop to advanced MDS and acute myelogenous leukemia. Approximately 15% of patients with FA are at risk for acute leukemia by the age of 35 yr.

Diagnosis
FA should be considered in all children and young adults with unexplained cytopenias. Abnormal hematologic findings and characteristic physical anomalies suggest the diagnosis, which is confirmed with a lymphocyte chromosomal breakage study using DEB. No other inherited pancytopenia is associated with a prominent in vitro hypersensitivity to DEB or mitomycin C by the chromosomal breakage study. Ten percent to 15% of patients with suspected FA have “somatic mosaicism” and their lymphocytes may not show characteristic high level of chromosomal fragility because of mixed populations of somatic cells, some with 2 abnormal alleles and some with 1 (caused by spontaneous somatic gene correction in a portion of the cells). Testing of skin fibroblasts instead of lymphocytes confirms the diagnosis.

Most patients have stable elevations of serum α-fetoprotein expressed constitutively, independent of liver complications or androgen therapy. Because of its low specificity compared to the chromosomal fragility and molecular tests the laboratory measurement of serum α-fetoprotein has not been widely used as a screening test.

As a result of the large number of FANC genes, genetic diagnosis has traditionally been commenced with complementation testing. This is done by determining whether cellular hypersensitivity to crosslinking agents (e.g., mitomycin C or radiation) or immunoblotting for FANCD2 is restored after generating hybridoma of the patient cells with known genetic complementation cells or after transducing the cells with a known FANC gene. The mutant gene or the complementation group is deduced when a specific wild-type FANC gene corrects the abnormal chromosome fragility.

Treatment
A hematologist and a multidisciplinary team should supervise patients with FA. If the hematologic findings are stable and there are no transfusion requirements, observation is indicated. Subspecialty consultations for anomalies and disabilities can be arranged during this interval. If growth velocity is below expectations, endocrine evaluation is needed to identify growth hormone deficiency or hypothyroidism. Screening for glucose intolerance and hyperinsulinemia should be performed annually or biannually, depending on the degree of hyperglycemia found on initial testing. Blood counts should be performed every 1-3 mo; bone marrow aspiration and biopsy are indicated annually for leukemia and MDS surveillance by means of morphology and cytogenetics. Patients should be assessed for solid tumors at least annually. Beginning at menarche, female patients should be screened annually for gynecologic cancer. Administration of human papilloma virus quadrivalent vaccine to prevent squamous cell carcinoma is currently advised.

Hematopoietic stem cell transplantation (HSCT; see Chapter 135) is the only curative therapy for the hematologic abnormalities. Patients <10 yr old with FA who undergo transplantation using an human leukocyte antigen (HLA)-identical sibling donor have a survival rate >80%. Survival rates are lower for patients >10 yr old who are undergoing the procedure. Preparative regimens are continuously evaluated, refined, and improved worldwide. For patients who do not have an HLA-matched sibling donor, a search for a matched unrelated donor (including a search of umbilical cord blood banks) might be initiated. Because of the need for more intensive preparation regimen and the heightened graft-versus-host response in patients with FA, the survival and cure rates have not been as good as those for matched sibling donor HSCT (>50% survival). Molecular technology has led to preplantation genetic diagnosis on parent-derived blastomers to find an HLA-matched sibling donor without FA.

Androgens produce a response in 50% of patients, heralded by reticuloctysis and a rise in hemoglobin within 1-2 mo. White blood cell counts may increase next, followed by platelet counts, but it may take many months to achieve the maximum response. When the response plateaus, androgen dosage can be slowly tapered but not stopped entirely. Oral oxymetholone is used most frequently once a day. The beneficial effect of adding low-dose prednisone to androgens is controversial, but when administered orally every second day, they may counter androgen-induced growth acceleration and prevent thrombocytopenic bleeding by promoting vascular stability. In many patients who are taking androgens, the disease becomes refractory as marrow failure progresses. Potential side effects include masculinization, elevated hepatic enzymes, cholestasis, peliosis hepatitis, and liver tumors. Screening for these changes should be performed serially.

The potential for recombinant growth factor (cytokine) therapy for FA has not been defined. Granulocyte colony-stimulating factor (G-CSF) can usually induce an increase in the absolute neutrophil count and occasionally may boost platelet counts and hemoglobin levels. There may be a heightened risk of expansion of marrow cells with clonal cytogenetic abnormalities such as monosomy 7. Combinatation therapy consisting of G-CSF given subcutaneously daily or every 2 days along with erythropoietin given subcutaneously or IV 3 times/wk results in improved neutrophil counts in almost all patients and a sustained rise in platelets and hemoglobin levels in approximately one-third of patients, although most patients lose the response after 1 yr owing to progression of marrow failure.

The premise for gene therapy in FA is based on the assumption that corrected hematopoietic cells offer a growth advantage. Attempts at gene therapy have been disappointing, possibly because of the type of vector but also because of the chromosomal fragility and impaired proliferative function of the hematopoietic progenitors. Encouraging preclinical data from studies using lentiviral vectors offer hope that gene therapy will be a safe and effective treatment for FA.

Prognosis
From FA cases reported in the 1990s, the projected median survival was >30 yr of age, an improvement over that in the previous decade. Successes with HSCT have dramatically improved the outlook. Careful surveillance for known complications, especially cancer, and prompt intervention on their detection has also contributed to the improved survival.

Chapter 468  The Inherited Pancytopenias  2365
SHWACHMAN-DIAMOND SYNDROME

Etiology and Epidemiology
Shwachman-Diamond syndrome (SDS) is inherited in an autosomal recessive manner; it occurs in all racial and ethnic groups. As FA, SDS is also a multisystem disorder. The nonhematologic manifestations are different and usually exclude exocrine pancreatic insufficiency and skeletal abnormalities such as metaphyseal dysplasia. There is no increased chromosomal breakage after DEB testing of SDS lymphocytes.

Pathology
The mutant gene SBDS maps to chromosome 7q11 and in 90% of cases is responsible for the multisystem, pleiotropic phenotype. The wild-type gene protein product is involved in ribosomal biogenesis. Pancreatic insufficiency is a result of failure of pancreatic acinar development. Fatty replacement of pancreatic tissue is prominent. Bone marrow failure is characterized by dysfunctional hematopoietic stem cells, accelerated apoptosis of marrow progenitors and a defective marrow microenvironment that does not support and maintain normal hematopoiesis.

Clinical Manifestations
Most patients with SDS have symptoms of fat malabsorption from birth that are caused by pancreatic insufficiency, but steatorrhea is not always obvious. Approximately 50% of patients appear to exhibit an improvement in pancreatic enzyme secretion as they age. The clinical picture can be dominated by complications from anemia, neutropenia, or thrombocytopenia. Bacterial and fungal infections secondary to neutropenia, neutrophil dysfunction, and immune deficiency can occur. Short stature is a consistent feature of the syndrome; most patients show normal growth velocity yet remain consistently below the 3rd percentile for height and weight. The occasional SDS adult achieves the 25th percentile for height. Although skeletal abnormalities are variable, classic findings are delayed bone maturation, metaphyseal dysplasia, short or flared ribs, and thoracic dystrophy. Some patients have hepatomegaly and elevations of liver enzymes. Most patients have dental abnormalities and poor oral health. Many have neurocognitive problems and poor social skills.

Laboratory Findings
Fatty replacement of pancreatic tissue can be visualized by CT scan or ultrasound. Fat malabsorption is proven by assay on a 72-hr stool collection. Pancreatic function tests show markedly impaired enzyme secretion, but with preservation of ductal function. Age-adjusted serum trypsinogen and isoamylase levels are reduced. Neutropenia is present in 100% of patients with SDS on at least 1 occasion. It can be chronic persistent or intermittent. It has been identified in some neonates during an episode of sepsis. Neutrophils may have a defect in mobility, migration, and chemotaxis owing to alterations in neutrophil cytoskeletal or microtubular function. Anemia, thrombocytopenia, and pancytopenia are seen in 66%, 60%, and up to 44% of cases, respectively. Pancytopenia can be severe as a result of full-blown aplastic anemia. Bone marrow biopsy specimens and aspirates usually show varying degrees of marrow hypoplasia and fat infiltration. Patients may also have B-cell defects with 1 or more of the following: low immunoglobulin G or immunoglobulin G subclasses, low percentage of circulating B lymphocytes, decreased in vitro B-cell proliferation, and lack of specific antibody production. Patients may have a low percentage of circulating T cells, subsets, or natural killer cells, and decreased in vitro T-cell proliferation.

Diagnosis
The clinical diagnosis of SDS relies on having an evidence of bone marrow dysfunction and exocrine pancreatic dysfunction. However, up to 20% of the patients may lack clear evidence of exocrine pancreatic defects at the time of diagnosis. Mutational analysis for SBDS is definitive in 90% of cases. Pearson syndrome (see Chapter 450), consisting of refractory sideroblastic anemia, cytoplasmic vacuolization of bone marrow precursors, lactic acidosis, exocrine pancreatic insufficiency, and a diagnostic mitochondrial DNA mutation is similar to SDS, but the clinical course, morphologic features of the bone marrow, and gene mutation are different. Also, severe anemia requiring transfusion, rather than neutropenia, is present from birth to 1 yr of age. SDS shares some manifestations with FA, such as marrow dysfunction and growth failure, but patients with SDS are readily distinguished because of pancreatic insufficiency with fat malabsorption, fatty changes within the pancreatic body that can be visualized by imaging, characteristic skeletal abnormalities not seen in FA, and a normal chromosomal breakage study with DEB.

Complications
Patients with SDS are predisposed to MDS and leukemic transformation. The crude rate of MDS or acute leukemia in patients with SDS is 8-33%. Marrow cell clonal cytogenetic abnormalities are an isolated finding, occurring in up to 41% of patients. Isochromosome 7 [i(7q)] is particularly common, suggesting that it is a fairly specific clonal marker of SDS and probably related to the presence of mutant SBDS on 7q11. Other clonal chromosome abnormalities include monosomy 7, i(7q) combined with monosomy 7, deletions or translocations involving part of 7q, and deletions of 20q [Del(20q)]. Although i(7q) and Del(20q) are rarely related to leukemic transformation or MDS, the prognostic significance of all marrow clonal changes requires prospective monitoring.

Treatment
Fat malabsorption responds to oral pancreatic enzyme replacement and supplemental fat-soluble vitamins, administered according to guidelines similar to those for cystic fibrosis (see Chapter 403). A long-term plan should be initiated to monitor changes in peripheral blood counts that require corrective action and to look for early evidence of malignant myeloid transformation. The latter requires serial bone marrow aspirations for smears and cytogenetics and marrow biopsy. One recommendation is to perform marrow testing every 1-2 yr and complete blood counts every 3 mo.

Daily subcutaneous G-CSF for profound neutropenia is effective in inducing a sustained increase in neutrophils. Some patients require transfusion support for management of severe anemia or thrombocytopenia. Experience with erythropoietin is limited. In some patients who received androgens plus steroids, blood counts have improved. The only curative option for severe marrow failure in SDS is allogeneic HSCT, although experience has been limited. Traditional myeloblastic HSCT resulted in treatment-related mortality in 35-50% of the patients. The risk of cardiotoxicity has been noted. Fludarabine-based protocols using reduced-intensity conditioning appear to be safer and effective for SDS HSCT.

Prognosis
The accurate life expectancy of SDS patients is unknown. Analysis of published cases revealed a median survival of 35 yr. Because the number of undiagnosed patients with mild or asymptomatic disease is unknown, the overall prognosis may be better than previously thought. Approximately 50% of patients experience spontaneous conversion from pancreatic insufficiency to pancreatic sufficiency as a result of improvement in pancreatic enzyme secretion. Enzyme replacement therapy is then no longer needed. Although all patients have some degree of hematologic cytopenia, the changes in most patients are mild to moderate and do not require therapeutic intervention. Severe neutropenia responds well to G-CSF, but there is concern that the predisposition to MDS and acute leukemia can be heightened by the agent's powerful growth stimulus on marrow cells. HSCT for severe marrow failure has produced a 50-70% survival rate, but safer protocols are being introduced. Malignant marrow transformation remains ominous.

DYSKERATOSIS CONGENITA

Etiology and Epidemiology
Dyskeratosis congenita (DC) is an inherited multisystem disorder characterized by mucocutaneous abnormalities, bone marrow failure,
and a predisposition to cancer and MDS. The diagnostic mucocutaneous (ectodermal) triad is reticulate skin pigmentation of the upper body, mucosal leukoplakia, and nail dystrophy (Fig. 468-2). Skin and nail findings usually become apparent in the 1st 10 yr of life, whereas oral leukoplakia is seen later. These manifestations tend to progress as patients get older. Varying degrees of bone marrow failure are seen in about 90% of the patients. Severe aplastic anemia occurs in approximately 50% of cases, usually in the 2nd decade of life. Many patients with DC are male, a finding compatible with the high frequency of the X-linked recessive form of the disease. The remainder have either an autosomal dominant or autosomal recessive mode of inheritance.

Pathology
DC is genetically heterogeneous, and patients have mutations in genes that encode components of the telomerase complex (DKC1, TERT, TERC, NOP10, and NHP2), T-loop disassembly protein (RTEL1), telomere capping (CTC1), the telomere shelterin complex (TINF2), and the telomerase trafficking protein (TCAB1), all components critical for telomere maintenance. The X-linked recessive form of DC maps to Xq28, and many mutations have been identified in the DKC1 gene, which codes for the nuclear protein dyskerin. The autosomal dominant form is due to mutations in TINF2, or in TERC or TERT, the RNA and enzymatic components of telomerase, respectively. Autosomal recessive DC is linked to mutations in NOP10, NHP2, RTEL1, TCAB1, and CTC1. Because of impaired telomere maintenance in all 3 inherited forms of DC, short telomeres are demonstrated in the peripheral blood cells of all patients and are a cardinal marker for DC and for marrow failure. The failure is likely a result of progressive attrition and depletion of hematopoietic stem cells because of premature senescence, which manifests as pancytopenia.

Clinical Manifestations
Skin pigmentation and nail changes typically appear first, mucosal leukoplakia and excessive ocular tearing appear later, and by the mid-teens, patients with DC have bone marrow failure and malignancy. Many female patients have the same features as male patients. In males, cutaneous findings are the most consistent feature. Lacy reticulated skin pigmentation affecting the face, neck, chest, and arms is a common finding (89%). The degree of pigmentation increases with age and can involve the entire skin surface. There may also be a telangiectatic erythematous component. Nail dystrophy of both hands and feet is the next most common finding (88%). It usually starts with longitudinal ridging, splitting, or pterygium formation and may progress to complete nail loss. Leukoplakia usually involves the oral mucosa (78%), especially the tongue but may also be seen in the conjunctiva and the anal, urethral, or genital mucosa. Hyperhidrosis of the palms and soles is common, and hair loss is sometimes seen. Eye abnormalities are observed in approximately 50% of cases. Excessive tearing (epiphora) secondary to nasolacrimal duct obstruction is common. Other ophthalmologic manifestations include conjunctivitis, blepharitis, loss of eyelashes, strabismus, cataracts, and optic atrophy. An increased rate of dental decay and early loss of teeth are common. Skeletal abnormalities, such as osteoporosis, avascular necrosis, abnormal bone trabeculation, scoliosis, and mandibular hypoplasia, are seen in approximately 20% of cases. Genitourinary abnormalities include hypoplastic testes, hypospadias, phimosis, urethral stenosis, and horseshoe kidney. Gastrointestinal findings, such as esophageal strictures, vascular lesions causing bleeding, hepatomegaly, and fibrosis are seen in 10% of cases. A subset of patients has pulmonary complications, with reduced diffusion capacity and/or a restrictive defect. In fatal cases, lung tissue shows pulmonary fibrosis and abnormalities of the pulmonary vasculature.

Laboratory Findings
The initial hematologic change in DC is usually thrombocytopenia, anemia, or both, followed by full-blown pancytopenia and aplastic anemia. The red cells are often macrocytic, and the fetal hemoglobin value can be elevated initially. Initial bone marrow specimens may be hypercellular, but with time, a symmetric depletion of all hematopoietic lineages ensues. Some patients have immunologic abnormalities, including reduced or elevated immunoglobulin values, decreased B- and/or T-lymphocyte count, and reduction of or absence of lymphocyte proliferative responses to phytohemagglutinin. This is particularly common and severe in the DKC1-associated disease. Primary skin...
fibroblasts in culture have abnormal morphologic features and doubling rate and show numerous unbalanced chromosome rearrangements, such as dicentrics, tricentrics, and translocations, in the absence of DEB. These findings provide evidence of a defect that predisposes patient cells to chromosomal rearrangements and possibly to DNA damage.

**Diagnosis**

The following abnormalities are seen in patients with DC but not in those with FA: nail dystrophy, leukoplakia, and tooth abnormalities, hyperhidrosis of the palms and soles, and hair loss (see Table 468-2).

There are overlap syndromes that share some of the features of DC. **Hoyeraal-Hreidarsson syndrome** is a multisystem disorder comprising aplastic anemia, immunodeficiency, microcephaly, growth retardation, and cerebellar hypoplasia. The syndrome is genetically heterogeneous; some cases are X-linked recessive and caused by mutations in **DKC1**, and others are autosomal recessive owing to homozygous **TERT** mutations. **Revesz syndrome** consists of dystrophic nails, leukoplakia, aplastic anemia, cerebellar hypoplasia, growth retardation, microcephaly, and bilateral exudative retinopathy. **TINF2** is mutated in Revesz syndrome, which hence is an autosomal dominant variant of DC. Coats’ plus syndrome is caused by mutations in the **CTCI** gene. It is characterized by retinal telangiectasia and exudates, intracranial calcification, leukodystrophy, brain cysts, osteopenia, gastrointestinal bleeding and portal hypertension caused by the development of varicose euctasias in the stomach, small intestine and liver. Some patients with this disease has the additional manifestations of DC, which include sparse and graying hair, dystrophic nails, and anemia. Telomeres are short.

**Complications**

Cancer develops in approximately 10-15% of patients with DC, usually in the 3rd and 4th decades of life. Patients with DC are predisposed to MDS as well as to solid tumors. Forty percent of the cancers in such patients are squamous cell carcinomas of the head and neck (tongue, mouth, pharynx). Cancer of the skin and gastrointestinal tract (esophagus, stomach, colon, and especially the anorectal site) is also common. Other life-threatening complications include pulmonary fibrosis and severe gastrointestinal bleeding.

**Treatment**

Androgens (with or without low-dose prednisone) can induce improvement of marrow function in approximately 50% of patients. When the response is maximal, the androgen dose can be slowly tapered but not stopped. DC can become refractory to androgens as the aplastic anemia progresses. There is no published information on the use of immunosuppressive therapy for this disorder, but the authors are aware of several patients who were misdiagnosed with acquired aplastic anemia and treated with immunosuppressive therapy without response. Although reports are scanty, cytokine therapy with granulocyte-macrophage colony-stimulating factor or with G-CSF alone or combined with erythropoietin appears to offer potential benefit, at least in the short term, especially for improving neutrophil numbers.

Allogeneic HSCT has been used to correct marrow failure in patients with DC, long-term survival is only 50%. Vascular lesions and fibrosis involving various organs are not prevented by HSCT and can occur early and late after transplantation; carrying a high mortality rate. Patients with DC may be more susceptible to endothelial damage that occurs after HSCT as a result of various factors, including the conditioning regimen, infectious disease, and graft-versus-host disease. Up to 40% of patients with DC experience fatal pulmonary complications after transplantation.

**Prognosis**

Considerable heterogeneity exists in DC. Patients with certain genetic groups (e.g., **TERC** and **TERT**) have milder clinical manifestations. Patients with other genetic groups (e.g., **DKC1**, **TINF2** and **BTEL1**) appear to have more physical anomalies and a higher incidence of aplastic anemia and cancer. The mean age of death for patients with DC who are diagnosed in childhood is approximately 30 yr. The main causes of death are bone marrow failure, complications of HSCT, cancer, fatal pulmonary problems, and gastrointestinal bleeding.

**CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA**

**Etiology and Epidemiology**

Congenital amegakaryocytic thrombocytopenia (CAMT) is the rarest of the 4 major inherited pancytopenias. It is transmitted in an autosomal recessive manner. CAMT manifests in infancy as isolated thrombocytopenia as a result of reduction or absence of marrow megakaryocytes with initial preservation of granulopoietic and erythrodielines. Megakaryocytes caused by aplastic anemia often ensues in the first few years of life. The defect in CAMT is directly related to mutations in **MPL**, the gene for the receptor of thrombopoietin, the growth factor that promotes hematopoietic stem cell survival and stimulates megakaryocyte proliferation and maturation. Carriers of the mutant gene have normal hematolgy; affected individuals have mutations in both alleles. Genotype–phenotype correlations predict disease course and prognosis. **Nonsense mutations** cause a complete loss of function of the thrombopoietin receptor, causing persistently low platelet counts because of the absence of megakaryocytes and a fast progression to pancytopenia and aplastic anemia (CAMT type I). Because thrombopoietin also has an antiapoptotic and cell survival effect on stem cells, impaired stem cell survival with **MPL** nonsense mutations explains the evolution of CAMT into aplastic anemia. **Missense mutations** of **MPL** are associated with a milder course, a transient increase in platelets during the 1st yr of life, and delayed onset, if any, of pancytopenia, indicating residual receptor function (CAMT type II). Biologically active plasma thrombopoietin is consistently elevated in all patients with CAMT.

**Clinical Manifestations**

Patients with CAMT have petechial rash, bruising, or bleeding at birth or in the 1st yr of life. Most, but not all, patients with proven **MPL** mutations have normal physical and imaging features. Approximately 20% of published phenotypic CAMT cases involved physical anomalies, but **MPL** mutation analyses were not available in all cases. The most common anomalies in the published cases are neurologic and cardiac. Findings related to cerebellar and cerebral atrophy are frequent, and developmental delay is a prominent feature. Congenital heart disease includes atrial septal defects, ventricular septal defects, patent ductus arteriosus, tetralogy of Fallot, and coarctation of the aorta. Some of these occur in combinations. Other anomalies include abnormal hips or feet, kidney malformations, eye anomalies, and cleft or high-arched palate. Some patients have microcephaly and an abnormal facies.

**Laboratory Findings**

Thrombocytopenia is the major laboratory finding in CAMT, with normal hemoglobin levels and white blood cell counts initially. Peripheral blood platelets are reduced or totally absent. As in other inherited bone marrow failure syndromes, red blood cells may be macrocytic. Hemoglobin F may be elevated, and there may be increased expression of i antigen. Initial bone marrow aspirates and biopsy specimens show normal cellularity with marked reduction or absence of megakaryocytes. In patients in whom aplastic anemia develops, marrow cellularity is decreased, with fatty replacement; erythropoietic and granulopoietic lineages are also symmetrically reduced.

**Diagnosis**

If thrombocytopenia persists beyond the neonatal period or is associated with adequate platelet transfusion response and no obvious precipitating cause such as infections or immunologic reactions, a marrow aspirate and biopsy is indicated. Deficient megakaryocytes in such cases suggest the diagnosis, and mutational analysis will confirm it. If CAMT occurs at birth or shortly after, it must be distinguished from other causes of inherited and acquired neonatal thrombocytopenia (see Chapter 484.8). Thrombocytopenia with absent radii (TAR syndrome) is distinguished from CAMT because in TAR syndrome the
radii are absent. The distinction from DC may be evident by mucocutaneous, neurologic, and immunologic findings that are characteristic to the early onset DC. CAMT blood lymphocytes do not show increased chromosomal breakage when exposed to DEB, distinguishing the disease it from FA.

Complications
In some patients, clonal marrow cell cytogenetic abnormalities appear such as monosomy 7 and trisomy 8. CAMT can evolve into MDS and also acute leukemia, but the true risk cannot be defined because of the rarity of the disease and the paucity of published data.

Therapy and Prognosis
The mortality rate in patients with MPL nonsense mutations from thrombocytopenic bleeding, complications of aplastic anemia, or leukemic transformation has been very close to 100%. Patients with missense mutations have a milder course but may still have serious complications. HSCT is the only curative option. The majority of patients with CAMT who undergo HSCT are cured, especially if the procedure is performed with HLA-matched sibling donors. Before transplantation, platelet transfusion should be used discretely. Platelet count should not always be the sole indication; clinical bleeding is an appropriate trigger. Single-donor filtered platelets are preferred to minimize sensitization. Leukodepleted platelet units might be adequate, but further studies are necessary to support such an alternative. In a patient for whom HSCT is a possibility, all blood products should be free of cytomegalovirus. Corticosteroids are not effective for treatment of the thrombocytopenia. For aplastic anemia, androgens may induce a temporary partial improvement. Interleukin-3 may be an important adjunct to the medical management of CAMT, but it was not adopted broadly and is no longer available. The role of thrombomimetic agents has to be studied; however, the induction of fibrosis by these agents and the risk of MDS/leukemia in CAMT render HSCT the preferred treatment for patients with severe cytopenia.

OTHER INHERITED SYNDROMES
Pancytopenia and bone marrow failure can occur in the context of several non-hematologic syndromes and familial settings that do not exactly correspond to the entities already described.

Down Syndrome
Down syndrome (trisomy 21; see Chapter 81.2) has a unique association with aberrant hematologic findings. In addition to the propensity for acute lymphoblastic and myeloblastic leukemias, especially acute megakaryoblastic leukemia, at least 6 patients with Down syndrome have been reported as having pancytopenia caused by aplastic anemia.

Dubowitz Syndrome
Dubowitz syndrome is an autosomal recessive disorder characterized by a peculiar facies, infantile eczema, small stature, and mild microcephaly. The face is small, with a shallow supraorbital ridge, a nasal bridge at the same level as the forehead, short palpebral fissures, variable ptosis, and micrognathia. There is a predilection to cancer as well as to bone marrow dysfunction in these patients. Approximately 10% of patients have hematopoietic disorders including moderate pancytopenia, hypoplastic anemia, bone marrow hypoplasia, and full-blown aplastic anemia. No gene mutation has been identified.

Seckel Syndrome
Seckel (SCKL) syndrome, sometimes called “bird-headed dwarfism,” is an autosomal recessive developmental disorder characterized by marked growth failure and mental deficiency, microcephaly, a hypoplastic face with a prominent nose, and low-set and/or malformed ears. Approximately 25% of patients have aplastic anemia or malignancies. There is broad genetic heterogeneity comprising 7 classifiable types: SCKL1, ATR mutation; SCKL2, RBBP8 mutation; SCKL3, maps to 14q21-q22; SCKL4, CENPf mutation; SCKL5, CEP152 mutation; SCKL6, CEP63 mutation; and, SCKL7, NIN mutation.

Reticular Dysgenesis
Reticular dysgenesis (see Chapter 126) is an immunologic deficiency syndrome coupled with congenital agranulocytosis. The mode of inheritance autosomal recessive in some cases; there is evidence that reticular dysgenesis is caused by homozygous or compound heterozygous mutation in the mitochondrial adenylate kinase-2 gene AK2 on chromosome 1p35 but an X-linked mode is also possible in some cases. The disorder is a variant of severe combined immune deficiency in which cellular and humoral immunity are absent and severe lymphopenia and neutropenia are also seen. Anemia and thrombocytopenia may also be present. Bone marrow specimens are hypocellular, with markedly reduced myeloid and lymphoid elements. The only curative therapy is HSCT.

Schimke Immunooossseous Dysplasia
Schimke immunooossseous dysplasia is an autosomal recessive disorder caused by mutations in the chromatin remodeling protein SMARCAL1. Patients have spondyloepiphyseal dysplasia with exaggerated lumbar lordosis and a protruding abdomen. There are pigmentary skin changes and abnormally discolored and configured teeth. Renal dysfunction can be problematic, with proteinuria and nephrotic syndrome. Approximately 50% of patients have hypothyroidism, 50% have cerebral ischemia, and 10% have bone marrow failure with neutropenia, thrombocytopenia, and anemia, and about 5% are predisposed to non-Hodgkin lymphoma. Lymphopenia and altered cellular immunity are present in almost all patients. In 2 published case reports, 2 patients underwent successful bone marrow transplantation.

Noonan Syndrome
Noonan syndrome is a developmental disorder characterized by the “Noonan facies” (hypertelorism, ptosis, short neck, low-set ears), short stature, congenital heart disease, and multiple skeletal and hematologic abnormalities. It is primarily an autosomal dominant disorder composed of at least 7 genetic types. Heterozygous mutations in PTPN11 cause approximately 50% of cases of the syndrome; others are caused by mutations in NF1, KRAS, SOS1, RAF1, NRAS, or BRAF. Autosomal recessive forms have also been identified due to a mutation of SHOC2 or of CBL. In addition to an association with juvenile myelomonocytic leukemia, Noonan syndrome patients can develop amegakaryocytic thrombocytopenia as well as pancytopenia with a hypocellular marrow.

Cartilage-Hair Hypoplasia
Cartilage-hair hypoplasia, an autosomal recessive syndrome seen mostly in Finnish or Amish populations, is characterized by metaphyseal dysostosis, short-limbed dwarfism, and fine, sparse hair. Additional skeletal findings are scoliosis, lordosis, chest deformity, and varus lower limbs. Gastrointestinal abnormalities also occur. Mutations in the RMRP gene cause cartilage-hair hypoplasia. Macrocytic anemia is seen in most patients and is sometimes severe and persistent. Neutropenia, lymphopenia, and a predisposition to lymphoma and other cancers are also features.

UNCLASSIFIED INHERITED BONE MARROW FAILURE SYNDROMES
Unclassified inherited bone marrow failure syndromes are heterogeneous disorders that may be either atypical presentations of identifiable diseases or new syndromes. Characterized by various cytopenias because of underproductive bone marrow with or without physical manifestations, they do not fit into a classic genetic bone marrow failure disease because all features may not be evident at the time of presentation. Compared with classic disorders (presentation ≤1 mo of age), infants with unclassified disorders present later (>9 mo) and manifest single or multilineage cytopenia, aplastic anemia, myelodysplasia, or malignancy with variable expression of malformations. Table 468-4 lists the criteria for the diagnosis. With follow-up, some may demonstrate typical physical features of known syndromes, such as SDS, although without obvious mutations in the SBDS gene.
Familial cases with aplastic anemia that cannot be readily classified into discrete diagnostic entities such as FA have been reported. When the patients present not early after birth and without physical malformations an acquired etiology cannot be ruled out. Detailed genetic testing for known inherited bone marrow failure syndrome genes or by whole exome or genome sequencing may identify an inherited etiology.

Bibliography
ETIOLOGY AND EPIDEMIOLOGY

Drugs, chemicals, toxins, infectious agents, radiation, and immune disorders can result in pancytopenia by direct destruction of hematopoietic progenitors, disruption of the marrow microenvironment, or immune-mediated suppression of marrow elements (Table 469-1). A careful history of exposure to known risk factors should be obtained for every child presenting with pancytopenia. Even in the absence of the classic associated physical findings, the possibility of a genetic predisposition to bone marrow failure should always be considered (see Chapter 468). The majority of cases of acquired marrow failure in childhood are “idiopathic,” in that no causative agent is identified. Many are probably immune-mediated through activated T lymphocytes and cytokine destruction of marrow progenitor cells. The overall incidence of acquired aplastic anemia is relatively low, with an approximate incidence in both children and adults in the United States and Europe of 2-6 cases/million population/yr. The incidence is higher in Asia, with as many as 14 cases/million population/yr in Japan.

Severe bone marrow suppression can develop after exposure to many different drugs and chemicals, including certain chemotherapeutic agents, insecticides, antibiotics, anticonvulsants, nonsteroidal antiinflammatory agents, and recreational drugs. Some of the most notable agents are benzene, chloramphenicol, gold, and, 3,4-methylenedioxymethamphetamine (Ecstasy).

A number of viruses can either directly or indirectly result in bone marrow failure. Parvovirus B19 is classically associated with isolated red blood cell aplasia, but in patients with sickle cell disease or immunodeficiency, it can result in transient pancytopenia (see Chapter 251). Prolonged pancytopenia can occur after infection with many of the hepatitis viruses, herpes viruses, Epstein-Barr virus (see Chapter 254), cytomegalovirus (see Chapter 255), and HIV (see Chapter 276).

Patients with evidence of bone marrow failure should also be evaluated for inherited forms of marrow failure, paroxysmal nocturnal hemoglobinuria (PNH; see Chapter 464), and collagen vascular diseases. Pancytopenia without peripheral blasts may be caused by bone marrow replacement by leukemic blasts or neuroblastoma cells.

PATHOLOGY AND PATHOGENESIS

The hallmark of aplastic anemia is peripheral pancytopenia, coupled with hypoplastic or aplastic bone marrow. The severity of the clinical course is related to the degree of myelosuppression. Severe aplastic anemia is defined as a condition in which 2 or more cell components have become seriously compromised (absolute neutrophil count <500/mm³, platelet count <20,000/mm³, reticulocyte count <1% after correction for hematocrit) in a patient whose bone marrow biopsy material is moderately or severely hypocellular. Approximately 65% of patients who first present with moderate aplastic anemia (absolute neutrophil count 500-1,500/mm³, platelet count 20,000-100,000/mm³, reticulocyte count <1%) eventually progress to meet the criteria for severe disease, if they are simply observed. Bone marrow failure may be a consequence of a direct cytotoxic effect on hematopoietic stem cells from a drug or chemical or may result from either cell-mediated or antibody-dependent cytotoxicity. There is strong evidence that many cases of idiopathic aplastic anemia are caused by an immune-mediated process, with increased circulating activated T lymphocytes producing cytokines (interferon-γ) that suppress hematopoiesis. Abnormal telomere

![Table 469-1](image-url)
length and telomerase activity in granulocytic precursors and increased expression of cell surface Flt3 ligand (a member of the class III receptor tyrosine kinase family) in the lymphocytes of patients with aplastic anemia suggest that early apoptosis of hematopoietic progenitors may play a role in the pathogenesis of this disease.

**CLINICAL MANIFESTATIONS, LABORATORY FINDINGS, AND DIFFERENTIAL DIAGNOSIS**

Pancytopenia results in increased risks of cardiac failure, infection, bleeding, and fatigue. Acquired pancytopenia is typically characterized by anemia, leukopenia, and thrombocytopenia in the setting of elevated serum cytokine values. Other treatable disorders, such as cancer, collagen vascular disorders, PNH, and infections that may respond to specific therapies (IV immune globulin for parvovirus), should be considered in the differential diagnosis. Careful examination of the peripheral blood smear for red blood cell, leukocyte, and platelet morphologic features is important. A reticulocyte count should be performed to assess erythropoietic activity. In children, the possibility of congenital pancytopenia must always be considered, and chromosomal breakage analysis should be performed to evaluate for Fanconi anemia (see Chapter 468). The presence of fetal hemoglobin suggests congenital pancytopenia but is not diagnostic. To assess for the possibility of PNH, flow cytometric analysis of erythrocytes for CD55 and CD59 is the most sensitive test. Bone marrow examination should include both aspiration and a biopsy, and the marrow should be carefully evaluated for morphologic features, cellularity, and cytogenetic abnormalities.

**TREATMENT**

The treatment of children with acquired pancytopenia requires comprehensive supportive care coupled with an attempt to treat the underlying marrow failure. For patients with an human leukocyte antigen–identical family member donor, allogeneic hematopoietic stem cell transplantation (HSCT) offers a 90% chance of long-term survival. The typical preparative regimen today consists of cyclophosphamide, fludarabine, and horse antithymocyte globulin (ATG). The risks associated with this approach include the immediate complications of transplantation, graft failure, and graft versus host disease. Late adverse effects associated with transplantation may include secondary cancers, cataracts, short stature, hypothyroidism, and gonadal dysfunctions (see Chapters 136–139). Only 1 in 5 patients has a human leukocyte antigen–matched sibling donor, so matched-related HSCT is not an option for the majority of patients.

For patients without a sibling donor, the major form of therapy is immunosuppression with horse ATG and cyclosporine, with a response rate of 70–80%. The median time to response is 6 mo. As many as 30% of responders experience relapse after discontinuation of immunosuppression, and some patients must continue cyclosporine for several years to maintain a hematologic response. Among those who relapse after immunosuppression, approximately 50% show response to a second course of ATG and cyclosporine. There is an increased risk (<10%) of clonal bone marrow disease, such as leukemia, myelodysplasia (MDS), or PNH after immunosuppression with karyotypic abnormalities most frequently involving chromosomes 6, 7, and 8. To accelerate neutrophil recovery, a hematopoietic colony-stimulating factor (e.g., granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor) is sometimes added to ATG and cyclosporine for treatment of patients with very severe neutropenia (absolute neutrophil count <200/mm³), but there is no clear evidence that this treatment influences response rate or survival. In a few cases, tacrolimus has been given successfully with ATG for treatment of aplastic anemia in patients unable to tolerate cyclosporine. Higher baseline reticulocyte count correlates with a higher probability of response to immunosuppression and survival. There is an inverse correlation between telomere length and the probability of relapse post-immunosuppression.

For patients who show no response to immunosuppression or who experience relapse after immunosuppression, matched unrelated HSCT and T-cell depleted haploidentical family member donor HSCT are treatment options, with a response rate approaching 90%. Cord blood transplants have been carried out in this refractory group of patients but there is a significant incidence of non-engraftment. High-dose cyclophosphamide has been used successfully in the treatment of patients with newly diagnosed aplastic anemia and in patients without adequate response to immunosuppression. This therapy leads to prolonged severe pancytopenia, increasing the risk of life-threatening infection, especially fungal. Other therapies that have been used in the past with inconsistent results include androgens, corticosteroids, and plasmapheresis. However, preliminary studies with eltrombopag (an oral thrombopoietin mimetic agent) have resulted in a hematologic response with improvements in platelet and neutrophil counts and hemoglobin levels in some patients. In patients who responded, bone marrow biopsies demonstrated trilineage normalization of hematopoiesis; some who were dependent on platelet or erythrocyte transfusions no longer needed transfusions.

**COMPLICATIONS**

The major complications of severe pancytopenia are predominantly related to the risk of life-threatening bleeding from prolonged thrombocytopenia or to infection secondary to protracted neutropenia. Patients with protracted neutropenia as a result of bone marrow failure are at risk not only for serious bacterial infections but also for invasive mycoses. Patients who have been transfused with red blood cells regularly over a long period are at increased risk of developing alloantibodies to red cell antigens and may require iron chelation therapy for transfusional iron overload. The general principles of supportive care that have evolved from the use of chemotherapy-related myelosuppression to treat patients with cancer should be fully extended to the care of patients with acquired pancytopenia.

**PROGNOSIS**

Spontaneous recovery from pancytopenia rarely occurs. If left untreated, pancytopenia has an overall mortality rate of approximately 50% within 6 mo of diagnosis and of >75% overall, with infection and hemorrhage being the major causes of morbidity and mortality. The majority of children with acquired severe aplastic anemia show response to allogeneic marrow transplantation or immunosuppression, leaving them with normal or near-normal blood cell counts.

**PANCYTOPENIA CAUSED BY MARROW REPLACEMENT**

Processes that either infiltrate or replace the bone marrow can manifest as acquired pancytopenia. Infiltration can be caused by malignancy (classically, neuroblastoma or leukemia) or occur as a consequence of myelofibrosis, MDS, or osteoporosis. Although uncommon, evidence of hypoplastic anemia can precede the onset of acute leukemia, generally by a few months. This relationship is important to appreciate in evaluating and monitoring children who present with what appears to be acquired aplastic anemia. Morphologic examination of the peripheral blood and bone marrow and marrow cytogenetic studies are critically important in making the diagnoses of leukemia, myelofibrosis, and MDS.

MDS is very rare in children, but when it occurs, its clinical course is more aggressive than the same category of MDS in adults. Pediatric MDS can be subdivided into refractory cytopenia of childhood (peripheral blasts <2% and marrow blasts <5%), refractory anemia with excess blasts (peripheral blasts 2-19% and/or marrow blasts 5-19%), and refractory anemia with excess blasts in transformation (peripheral and/or marrow blasts 20-29%). Disease in children with >30% blasts is usually defined as acute myelocytic leukemia.

A number of inherited conditions are associated with an increased risk for development of MDS, including Down syndrome, severe congenital neutropenia, Noonan syndrome, Fanconi anemia, trisomy 8 mosaicism, neurofibromatosis, and Shwachman syndrome. Significant clonal abnormalities are found within the marrow of approximately 50% of patients with MDS, with monosomy 7 and being most common but prognostically neutral. Those with a structurally complex karyotype have a very poor outcome.
The transition time from pediatric MDS to acute leukemia is relatively short, at 14-26 mo, so aggressive treatment, such as HSCT, must be considered shortly after diagnosis. With allogeneic HSCT, the survival rate is approximately 60%. One exception to such an aggressive therapeutic approach is MDS and acute myelocytic leukemia in children with Down syndrome, because this disease in this specific population is very responsive to conventional chemotherapy, with long-term survival rates >80%.

The decision on how to treat a child with MDS who lacks a suitable hematopoietic stem cell donor should be made with the specific clonal abnormality found within the child's marrow taken into consideration. Lenalidomide produces the best responses among patients who have the chromosomal abnormality, 5q−. Immunosuppressive therapy with ATG and cyclosporine is most effective in patients with trisomy 8, especially in the presence of a PNH clone. Imatinib mesylate targets mutations in the tyrosine kinase receptor family of genes found in patients with t(5;12) and del(4q12). The DNA hypomethylating agents azacitidine and decitabine have also been used in treating MDS without a known molecular target and have some effect.

Bibliography
Red blood cells (RBCs) are transfused to increase the oxygen-carrying capacity of the blood, with the goal to increase or maintain satisfactory tissue oxygenation; this goal may not be achieved simply by increasing the blood hemoglobin concentration or hematocrit by an RBC transfusion because tissue oxygenation depends on several additional factors including oxygen off-loading from RBCs, microvascular blood flow, and diffusion of oxygen into tissue cells. Although some attempts have been made to accurately relate posttransfusion blood hemoglobin concentration or hematocrit values to changes in posttransfusion tissue oxygenation (e.g., improvements in the ratio of cerebral versus mesenteric oxygenation patterns assessed by serial near-infrared spectrosopic measurements), decisions to transfuse RBCs per physiologic indications, rather than degree of anemia, remain investigational.

Because neonates, especially extremely low birthweight preterms are not “small” children (i.e., RBC physiology and the pathophysiology of the anemia of prematurity are unique), RBC transfusions for neonates and older children will be considered separately. Guidelines for RBC transfusions in children and adolescents are based on maintaining a specified hemoglobin or hematocrit level considered to be optimal (per the best evidence available) for the clinical condition present at the time of the transfusion. The guidelines are similar to those for adults (Table 470-1). Transfusions may be given more stringently to children, because normal hemoglobin levels are lower in healthy children than in adults and, as is often the case, children do not have the underlying multiorgan, cardiorespiratory, and vascular diseases that develop with aging in adults to suggest a need for RBC transfusions. Thus, children may compensate better for RBC loss than elderly adults and, as is true for patients of all ages, there is increasing enthusiasm for applying conservative practices (i.e., accept lower pretransfusion hematocrit values to “trigger” an RBC transfusion).

In the perioperative period, it is unnecessary for most children to maintain hemoglobin levels of 8 g/dL or greater, a level frequently desired for adults. The desired preoperative hemoglobin level should take into account the estimated blood loss for the surgical procedure planned and the rate of bleeding. There should be a compelling reason to prescribe any postoperative RBC transfusion, such as continued bleeding with hemodynamic instability, because most children (without continued bleeding) can, in a relatively short time, restore their RBC mass with iron therapy. The most important measures in the treatments of acute hemorrhage are to control the hemorrhage and, if blood loss is modest, to restore the circulating blood volume and tissue perfusion with crystalloid or, less often, colloid solutions. If the estimated blood loss is >25% of the circulating blood volume (>0.15 mL/kg of an estimated 60 mL/kg total estimated blood volume) and the patient’s condition is unstable despite intravenous fluids, RBC transfusions may be indicated; given with plasma transfusions at a 1:1 ratio of RBC:plasma volumes. Details of combined RBC and plasma transfusions, the volume ratio transfused, and considerations for adding platelet transfusions to treat bleeding patients are controversial. Accordingly, each hospital should develop and follow a “massive transfusion” protocol to ensure consistent practices.

In critically ill children with severe cardiac or pulmonary disease requiring assisted ventilation, it is common practice to maintain the hemoglobin level close to the normal range, although the efficacy of this practice has not been well documented. A similar approach is used for children with acute cardiac, pulmonary, or cardiopulmonary disorders managed with extracorporeal membrane oxygenation.

The pretransfusion blood hemoglobin level or hematocrit that should “trigger” a RBC transfusion is controversial (i.e., restrictive or a low pretransfusion level vs. liberal or a high pretransfusion level)

<sup>†</sup>Words in italics must be defined for local transfusion guidelines.  <sup>†</sup>Pretransfusion blood hemoglobin level (convert to hematocrit values if preferred by multiplying hemoglobin values by 3)” triggering” an RBC transfusion. Hemoglobin values to maintain vary among published reports, and the guideline values to maintain should be determined locally to fit the practices judged to be optimal by local MDs.
A key reason that the nadir hemoglobin values of premature infants are lower than those of term infants is the former group's relatively diminished plasma EPO level in response to anemia (see Chapters 103.1 and 446). Another factor is the rapid disappearance of EPO from infant plasma (i.e., accelerated metabolism).

Low plasma EPO levels provide a rationale for the possible use of recombinant EPO in the treatment of anemia of prematurity; treatment with EPO and iron effectively stimulate neonatal erythropoiesis. Despite its erythropoietic effect, the efficacy of EPO therapy to substantially diminish the need for RBC transfusions has not been convincingly demonstrated, particularly for sick, extremely premature neonates, and recombinant EPO has not been widely accepted as a treatment for anemia of prematurity (see Chapter 103.1).

Because of the controversies over recombinant EPO therapy, many low birthweight preterm infants need RBC transfusions (see Table 470-1). Although the practice to maintain a very high hemoglobin level (hemoglobin >13 g/dL or hematocrit >40%) was once widely recommended, currently more restrictive guidelines have been suggested. Consistent with the rationale for oxygen delivery in neonates with severe respiratory disease, it seems appropriate to keep the hemoglobin value relatively high in neonates with severe cardiac disease leading to either cyanosis or congestive heart failure, but convincing and consistent data are lacking.

The optimal hemoglobin level for neonates facing major surgery has not been established. However, it seems reasonable to begin surgery in neonates with the hemoglobin level no lower than 10 g/dL (hematocrit >30%) and to maintain that value during major surgery because even modest blood loss will have a relatively large effect on the small blood volume of the neonate; neonates with underlying pulmonary problems have limited ability to compensate for anemia, and the inferior offloading of oxygen because of the diminished interaction between fetal hemoglobin and 2,3-diphosphoglycerate. Postoperatively, a lower pretransfusion hemoglobin value should be followed to "trigger" a transfusion.

Stable neonates do not require RBC transfusion, regardless of their blood hemoglobin levels, unless they exhibit clinical symptoms attributable to anemia. Proponents of RBC transfusions for symptomatic anemia in preterm neonates believe that the low RBC mass contributes to tachypnea, dyspnea, tachycardia, apnea and bradycardia, feeding difficulties, and lethargy, which can be alleviated by transfusion of RBCs. However, anemia is only one of several possible causes of these problems, and RBC transfusions should only be given when clinical benefit seems likely.

The RBC product of choice to transfuse neonates, infants, children, and adolescents is prestorage leukocyte-reduced RBCs suspended in an anticoagulant/preservative storage solution at a hematocrit value of approximately 60% for storage up to 42 days. The usual dose is 10-15 mL/kg, but transfusion volumes vary greatly, depending on clinical circumstances (continued vs. arrested bleeding, hemolysis). For neonates, some prefer a centrifuged RBC concentrate (hematocrit 70-90%). Unless transfusions are being given to treat rapid bleeding, RBCs are infused slowly (over 2-4 hr) at a dose of approximately 15 mL/kg. In this small-volume setting, because of the small quantity of extracellular fluid transfused and the slow rate of infusion, the type of RBC anticoagulant/preservative solution does not pose any risk for premature infants; there are no data to justify separate inventories of different RBC products for neonates and infants (e.g., citrate-phosphate-dextrose or citrate-phosphate-dextrose-adenine) versus older children (e.g., AS-1, AS-3, or AS-5).

The historical practice of transfusing fresh RBCs (<7 days of storage) for the small-volume (15 mL/kg) transfusions commonly given was supplanted several years ago in most centers by reserving a single unit of RBCs for an infant, from which multiple aliquots were obtained for transfusions as needed throughout the 42 days of storage. Concerns about high concentrations of extracellular potassium, loss of 2,3-diphosphoglycerate, altered RBC shape and deformability, and nitric oxide quenching were found not to pose clinically significant problems. Preterm neonates allocated to "fresh RBC" (<7 day storage) transfusions versus "stored RBC" (up to 42 day storage) transfusions,
have no advantage for fresh RBC transfusions in altering either the composite clinical outcome of mortality plus necrotizing enterocolitis, retinopathy of prematurity, bronchopulmonary dysplasia, and intraventricular hemorrhage or of the individual disorders.

For children weighing >30 kg who are to undergo elective surgery for which RBC transfusions are likely to be needed, autologous RBC transfusions offer an alternative to donor allogeneic RBCs. Preoperative autologous blood collections from the patient occur up to 6 wk before the surgery and require careful considerations for the volume to be drawn, vascular access, and use of EPO and iron to help restore the donated RBCs. Acute normovolemic hemodilution occurs in the preoperative period, in which blood is withdrawn from the patient and replaced with saline, a task often difficult in centers without experience in the process. Salvaged autologous blood is collected from blood loss during the operation but is impractical unless the volume of blood salvaged is fairly large to permit washing and transfusion of a significant number of RBCs. Because of all of these difficulties plus the relative safety of the usual allogeneic blood supply, autologous RBC transfusions are not commonly used in the pediatric setting.

Bibliography is available at Expert Consult.
Bibliography
Guidelines for platelet (PLT) support of children and adolescents with quantitative and qualitative PLT disorders are similar to those for adults (Table 471-1), in whom the risk of life-threatening bleeding after injury or occurring spontaneously can be related somewhat precisely, particularly for the occurrence of spontaneous bleeding to the severity of thrombocytopenia.

For children and adolescents with overt bleeding, therapeutic PLT transfusions should be given when the blood PLT count falls below $50 \times 10^9/L$ and repeated as needed to maintain the PLT count $>50 \times 10^9/L$ during bleeding and for 48 hr after bleeding ceases to allow the clot to “stabilize.” Similarly, for a major invasive procedure (e.g., surgical procedure), the PLT count should be maintained $>50 \times 10^9/L$ until any bleeding that occurs ceases and the patient is stable. For minor invasive procedures (e.g., lumbar puncture or placing an intravascular catheter) practices vary, but it is reasonable to maintain the PLT count $>25 \times 10^9/L$.

Historical studies of patients with thrombocytopenia resulting from bone marrow failure suggest that the risk of spontaneous bleeding increases when blood PLT levels fall to $<20 \times 10^9/L$ particularly when hemorrhagic risk factors (infection, organ failure, clotting abnormalities, minor skin/mucosal bleeding, mucosal lesions, severe graft-versus-host disease, or anemia) are present. In this high-risk setting, prophylactic PLT transfusions are given to maintain a PLT count $>20 \times 10^9/L$. This threshold has been challenged by several studies of adult patients, who, in many instances, were carefully selected to be in relatively good clinical condition without hemorrhagic risk factors. Consequently, a higher PLT transfusion trigger of $50 \times 10^9/L$ is recommended for stable (i.e., low-risk) patients.

In practice, severe thrombocytopenia that is prolonged beyond 1 wk commonly becomes complicated by the development of risk factors including fever, antimicrobial therapy, graft-versus-host disease, active bleeding, need for an invasive procedure, disseminated intravascular coagulation, and liver or kidney dysfunction with clotting abnormalities. In these situations, prophylactic PLT transfusions are given to maintain relatively high PLT counts (e.g., at least $>30 \times 10^9/L$). Despite the desire by some physicians to elevate the blood PLT count to $80 \times 10^9/L$ or $100 \times 10^9/L$, there are no definitive data to justify a true benefit of PLT transfusions given at a PLT count $>50 \times 10^9/L$, unless bleeding is ongoing with a PLT count between 50 and $100 \times 10^9/L$ and thrombocytopenia seems to be the only cause for the bleeding.

Qualitative PLT disorders may be inherited or acquired (in advanced hepatic or renal insufficiency or when blood flows through an extracorporeal circuit, such as during extracorporeal membrane oxygenation or cardiopulmonary bypass). In patients with inherited disorders, PLT transfusions are justified only if the risk of significant bleeding is quite high or if bleeding is overt because inherited PLT dysfunction often is lifelong and repeated transfusions may lead to alloimmunization and refractoriness (i.e., poor response to PLT transfusions). Accordingly, prophylactic PLT transfusions are rarely justified, unless an invasive procedure is planned, and therapeutic PLT transfusions must be given judiciously.

When managing patients with PLT dysfunction, it is important to remember that, an abnormal test result with a modern PLT function device or, historically, a bleeding time more than twice the upper limit of normal provides diagnostic evidence of PLT dysfunction. However, an abnormal bleeding time or any other abnormal laboratory test is poorly predictive of hemorrhagic risk and/or the need to transfuse PLTs. Alternative therapies, particularly desmopressin acetate, should be considered to avoid PLT transfusions. Antiplatelet medications (nonsteroidal antiinflammatory drugs) should also be avoided.

In neonates, thrombopoiesis and the risks of bleeding are substantially different from that in older children; the approach to thrombocytopenia and PLT transfusions likewise differs (see Table 471-1). Thrombopoietin (TPO) levels are higher in healthy neonates than in older individuals. Megakaryocyte progenitors of neonates are more sensitive to TPO, have higher proliferative potential, and give rise to larger megakaryocyte colonies than do adult PLT progenitors. Fetal/neonatal megakaryocytes are smaller in size and have lower ploidy than do their adult counterparts; this is an important factor because small megakaryocytes of low ploidy produce fewer PLTs than larger megakaryocytes of higher ploidy. Presumably, this allows the expanding marrow of the growing fetus and neonate to be supplied with sufficient numbers of megakaryocytes, yet not allowing blood PLT counts to become excessively high during proliferation, because of the lower numbers of PLTs produced by each megakaryocyte. An important contrasting point is that older children and adults respond to situations of increased demand for PLTs by first increasing megakaryocyte size and ploidy, which is followed in 3-5 days by
increased megakaryocyte number. In thrombocytopenic neonates, megakaryocyte numbers increase, but not their size. Moreover, although cytoplasmic maturation is achieved per TPO stimulation, increases in ploidy are relatively diminished and actually appear to be inhibited by TPO, resulting in large numbers of small megakaryocytes that are cytoplasmically mature, but with low ploidy and, consequently, lower PLT production.

Blood PLT counts ≥150 × 10^9/L are present after 17 wk gestational age, and it is accepted that neonates have blood PLT counts in the same range as older children and adults (150,000-450,000/µL). However, recent data suggest a lower limit of 120,000/µL for extremely small preterm infants. Approximately 1% of term infants demonstrate PLT counts <150 × 10^9/L, but bleeding in such infants is rare. In contrast, 25-35% of preterm of neonates treated in intensive care units exhibit blood PLT counts <150 × 10^9/L at some time during admission, with approximately 4% overall receiving PLT transfusions. Notably, when only extremely low birthweight perterm infants (<1 kg birthweight) were considered in one report, 73% had PLT counts <150 × 10^9/L and 62% of thrombocytopenic neonates received PLT transfusions. Multiple pathogenetic mechanisms underlie thrombocytopenia in these sick neonates; predominantly accelerated PLT destruction plus diminished PLT production, as evidenced by decreased numbers of megakaryocyte progenitors and relatively low upregulation of TPO levels during thrombocytopenia, compared with thrombocytopenic children and adults.

Blood PLT counts <100 × 10^9/L pose significant clinical risks for premature neonates. Bleeding time may be prolonged at PLT counts <100 × 10^9/L in infants with a birthweight <1.5 kg, and PLT dysfunction is suggested by bleeding times (a test no longer performed) that are disproportionately long for the degree of thrombocytopenia. The risk of hemorrhage may be increased in thrombocytopenic infants. However, in a randomized trial, transfusing PLTs prophylactically whenever the PLT count fell to <150 × 10^9/L (i.e., at the lower limit of the normal range) to maintain the average PLT count at >200 × 10^9/L, compared to not transfusing PLTs until the PLT count fell to <50 × 10^9/L to maintain the average PLT count at approximately 100 × 10^9/L, did not result in a lower incidence of intracranial hemorrhage (28% vs. 26%, respectively). Thus, there is no documented benefit for prophylactic PLT transfusions to maintain PLT counts within the normal range or to correct modest thrombocytopenia (PLT count ≥50 × 10^9/L).

As an exception, infants with inherited PLT dysfunction disorders and bleeding, and those at high risk of bleeding owing to acquired PLT dysfunction, such as during extracorporeal membrane oxygenation, commonly receive transfusions to keep their PLT counts >100 × 10^9/L.

Table 471-1 lists guidelines that are acceptable to many neonatologists. One particularly contentious issue is how to manage critically ill neonates receiving drugs/agents known to adversely affect PLT function (e.g., indomethacin, nitric oxide, antibiotics). Some reports suggest increased risk of bleeding for these neonates, but the efficacy of PLT transfusions has not been convincingly proven, particularly when given prophylactically. For optimal PLT transfusion practices, each hospital should modify the guidelines to comply with local practices, and audits/reviews should be performed to avoid violations of the recommended practices. The posttransfusion goal of most PLT transfusions is to raise the PLT count well above 50 × 10^9/L, hopefully to ≥100 × 10^9/L. These increases can be achieved consistently in children weighing up to 30 kg by infusion of 5-10 mL/kg of standard (unmodified) PLT concentrates, obtained either from processing whole blood units or by plateletpheresis. For larger children, the appropriate dose is 3-4 pooled whole blood–derived PLT units or 1 apheresis unit. Because PLT concentration/quantity varies in different PLT products made available for transfusion, each hospital should monitor posttransfusion PLT counts to determine the dose that works best locally. PLT concentrates should be transfused as rapidly as the patient’s overall condition permits, certainly within 2 hr. Neonates/infants requiring repeated PLT transfusions should receive leukocyte-reduced blood products, including PLT concentrates, to diminish alloimmunization and PLT refractoriness and to reduce the risk of transfusion-transmitted cytomegalovirus infection.

Routinely reducing the volume of PLT concentrates for infants and small children by additional centrifugation steps is both unnecessary and unwise. Transfusion of 10 mL/kg of an unmodified PLT concentrate is adequate because it adds approximately 10 × 10^9 PLTs to 70 mL of blood (the estimated intravascular blood volume of a 1 kg neonate), a dose/volume calculated to increase the PLT count by 100 × 10^9/L. This calculated increment is consistent with actual posttransfusion increment reported in patients. Moreover, 10 mL/kg is not an excessive transfusion volume, provided that the intake of other IV fluids, medications, and nutrients is monitored and adjusted.

It is important to select PLT units for transfusion with the donor ABO group identical to that of the neonate/infant and to avoid repeated transfusion of group O PLTs to group A or B recipients because passive transfusion anti-A or anti-B in group O plasma, can occasionally lead to hemolysis.

Table 472-1 lists guidelines for granulocyte transfusion (GTX). GTX has been used sparingly in older infants and children. The current ability to collect markedly higher numbers of neutrophils from donors stimulated with combined recombinant granulocyte colony-stimulating factor (G-CSF) plus dexamethasone has led to renewed interest for patients with neutropenic infections, particularly when severe neutropenia is prolonged (e.g., in the setting of placental/cord blood hematopoietic progenitor cell transplantation). Because of the higher neutrophil yields with this collection approach, adding GTX to antibiotics should be considered at institutions where neutropenic patients continue either to die of progressive bacterial and fungal infections or to suffer substantial morbidity despite optimal antiinfection measures, including antibiotics and recombinant myeloid growth factors.

The use of GTX added to antibiotics for children with severe neutropenia (blood neutrophil count $< 0.5 \times 10^9/L$) because of bone marrow failure is similar to that for adults. Unfortunately, two randomized clinical trials comparing antibiotics plus GTX from donors stimulated with G-CSF plus dexamethasone versus antibiotics without GTX

to treat neutropenic infections in children have not provided definitive guidelines. However, in practice, neutropenic patients with bacterial infections usually show response to antibiotics alone, provided bone marrow function recovers within the first 7-10 days of infection onset so that severe neutropenia is relatively brief. Children with newly diagnosed acute lymphoblastic leukemia show rapid response to induction chemotherapy, and they rarely are candidates for GTX. In contrast, infected children with more sustained bone marrow failure and consequent severe neutropenia (e.g., acute myeloblastic leukemia, malignant neoplasms resistant to treatment, severe aplastic anemia, and placental/cord blood hematopoietic progenitor cell transplant recipients) may benefit when GTX is added to antibiotics.

Currently, the efficacy of GTX obtained from G-CSF plus dexamethasone-stimulated donors for bacterial sepsis unresponsive to antibiotics in patients with severe neutropenia (blood neutrophil count <0.5 × 10^9/L) is not well supported by trials in children. In contrast, GTX efficacy for yeast and fungal infections remains unproven despite transfusing GTX with relatively large numbers of neutrophils.

Children with qualitative neutrophil defects (neutrophil dysfunction) usually have adequate or even increased numbers of blood neutrophils but suffer serious infections, because their neutrophils kill pathogenic microorganisms inefficiently. Neutrophil dysfunction syndromes are rare; accordingly, no definitive studies have established GTX efficacy. However, several patients with progressive life-threatening infections have shown striking improvement with the addition of GTX, often given for long periods of time, to antimicrobial therapy. These disorders are chronic, and because of the risk of inducing alloimmunization to leukocyte antigens, and in some patients with chronic granulomatous disease, to antigens of the Kell system of red blood cells, GTX is recommended only when serious infections are clearly unresponsive to antimicrobial drugs.

Neonates are unusually susceptible to severe bacterial infections, and a number of defects of neonatal body defenses contribute, including actual or “relative” neutropenia. Neonates with fulminant sepsis who exhibit relative neutropenia (blood neutrophil count <3.0 × 10^9/L during the first week of life and <1.0 × 10^9/L thereafter) and a severely diminished neutrophil marrow storage pool (with <10% of nucleated marrow cells being postmitotic neutrophils) are at risk of dying if treated only with antibiotics. GTX is rarely used because results of clinical trials are mixed and not uniformly convincing, and it is difficult to obtain neutrophil apheresis concentrates in timely fashion.

Current data are insufficient to determine whether recombinant myeloid growth factors have a role in treating septic neonates, despite the fact that both G-CSF and granulocyte-macrophage colony-stimulating factor have been demonstrated to enhance myelopoiesis and raise neutrophil counts in infants. Importantly, G-CSF is efficacious for the long-term treatment of several types of severe congenital neutropenia.

If the decision to provide a GTX has been made, an adequate dose of neutrophils/granulocytes collected by leukapheresis must be transfused as shortly after collection as possible. To facilitate this, experienced donors with required infectious disease (HIV, hepatitis) tests having been done recently (usually within the past 30 days) are selected, and the collected neutrophils are transfused before results of current infectious disease tests are known (i.e., infectious disease test results are “waived”).

Neonates and infants weighing <10 kg should receive 1-2 × 10^9/kg neutrophils per each GTX. Larger infants and small children should receive a minimal total dose of 1 × 10^10 neutrophils per each GTX. The preferred dose for adolescents is 5-8 × 10^10 neutrophils per each GTX, a dose requiring donors to be stimulated with G-CSF plus dexamethasone. GTX should be given daily until either the infection resolves or the blood neutrophil count is sustained above 1.5 × 10^9/L for a few days. Because neutrophils transfused per the GTX often passively increase the blood neutrophil count, it may be necessary to skip 1-2 days of GTXs to be certain severe neutropenia does not recur, as would be seen if endogenous myelopoiesis had not recovered.

Guidelines for plasma transfusion in pediatric patients (Table 473-1) are similar to those for adults but with the understanding that plasma levels of coagulant and anticoagulant proteins can be developmentally quite low in preterm infants so that transfusions of plasma and plasma-derived commercial concentrates should be determined by actual bleeding or a significant risk of bleeding, not simply prolonged clotting time results. Plasma is transfused to replace clinically significant deficiencies of plasma proteins for which more highly purified protein concentrates that have been treated to reduce infectious disease risks are not available nearly always to provide clotting proteins when bleeding is occurring or in settings when prevention of bleeding is deemed critical.

Two interchangeable plasma products are available for transfusion, plasma frozen within 8 hr of collection (fresh-frozen plasma) and plasma frozen within 24 hr of collection. Although levels of factors V and VIII are modestly reduced in the latter plasma product (generally, not more than 25% lower), they are equally efficacious for all indications for which plasma is transfused (see Table 473-1). Recommendations for the volume of plasma to be transfused vary with the specific protein being replaced and the severity of the deficiency, but a starting dose of 15 mL/kg is usually sufficient to elevate plasma levels satisfactorily.

Transfusion of plasma is efficacious for the treatment of deficiencies of clotting factors II, V, X, and XI. Deficiencies of factor XIII and fibrinogen are treated either with cryoprecipitate or specific commercial concentrates; although for patients being given large doses of plasma (e.g., in massive transfusion settings or to treat bleeding in liver failure), additional sources of fibrinogen may not be necessary, as plasma contains large amounts of fibrinogen. It is always useful to include a measurement of plasma fibrinogen when performing clotting assays (e.g., prothrombin time [PT]/international normalized ratio [INR] and activated partial thromboplastin time [aPTT]). Transfusion of plasma is not recommended for the treatment of patients with severe hemophilia A or B, von Willebrand disease, or factor VII deficiency, because safer factors VII, VIII, IX, and von Willebrand factor concentrates are available. Moreover, mild to moderate hemophilia A and certain types of von Willebrand disease can be treated with intranasal or intravenous desmopressin (see Chapter 477). An important use of plasma is for rapid reversal of the effects of warfarin in patients who are actively bleeding or who require emergency surgery (in whom

functional deficiencies of factors II, VII, IX, and X cannot be rapidly reversed by vitamin K). Prothrombin “complex” concentrates can also be used for this purpose.

Results of screening coagulation tests (PT/INR, aPTT, and thrombin times, and plasma fibrinogen levels) should not be assumed by themselves to reflect the integrity of the coagulation system or be regarded as indications for plasma transfusions. This is particularly true for neonates. To justify plasma transfusions, coagulation test results must be related to the patient's clinical condition pertaining to bleeding and/or the risk of bleeding. Transfusion of plasma in patients with chronic liver disease and prolonged clotting times is not recommended unless bleeding is present or an invasive procedure is planned, because correction of the clotting factor deficiencies is brief and of questionable benefit.

Plasma also contains several anticoagulant proteins (antithrombin III, protein C, and protein S) whose deficiencies have been associated with thrombosis. In selected situations, plasma may be appropriate as replacement therapy, along with anticoagulant treatment, in patients with these disorders; when available, purified concentrates are preferred. Other indications for plasma include replacement fluid during plasma exchange in patients with thrombotic thrombocytopenic purpura (i.e., thrombotic microangiopathies) or other disorders for which plasma is likely to be beneficial (plasma exchange in a patient with overt bleeding due to the underlying disorder such as Goodpasture syndrome or vasculitis or disorders with significant severe coagulopathy that would be made substantially more severe by replacement using albumin solutions only). Plasma is not indicated for correction of hypovolemia or as immunoglobulin replacement therapy, because safer alternatives exist (albumin or crystalloid solutions and IV immunoglobulin, respectively).

In neonates, clotting times are “physiologically” prolonged owing to developmental deficiency of clotting proteins; plasma should be transfused only after reference to normal values adjusted for the birthweight and age of the infant (i.e., not to normal ranges for older children and adults). The indications for plasma in neonates include: (1) reconstitution of red blood cell (RBC) concentrates to simulate whole blood for use in massive transfusions (exchange transfusion, cardiac bypass surgery, and extracorporeal membrane oxygenation); (2) hemorrhage secondary to vitamin K deficiency; (3) disseminated intravascular coagulation with bleeding; and (4) bleeding in congenital coagulation factor deficiency when more specific treatment is either unavailable or inappropriate. The use of prophylactic plasma transfusion to prevent intraventricular hemorrhage in premature infants is not recommended. Plasma should not be used as a suspending agent to adjust the hematocrit values of RBC concentrates before small-volume RBC transfusions to neonates because it offers no apparent medical benefit over the use of sterile solutions such as crystalloid and albumin. Similarly, the use of plasma in partial exchange transfusion for the treatment of neonatal hyperviscosity syndrome is unnecessary, because safer crystalloid or colloid solutions are available.

In the treatment of bleeding infants, cryoprecipitate is often considered because of its small infusion volume. However, cryoprecipitate contains significant quantities of only fibrinogen, von Willebrand factor, and factors VIII and XIII. Thus, it is not effective for treating the usual clinical situation in bleeding infants in which multiple clotting factor deficiencies exist.

In preliminary studies, infusions of very small volumes of recombinant activated factor VII have been lifesaving in patients with hemorrhage caused by several mechanisms. Because the efficacy and toxicity of factor VIIa have not been fully defined in these “off-label” uses (not approved by the U.S. Food and Drug Administration), it must be considered experimental therapy at this time.

The greatest risk of a blood transfusion is receiving a transfusion intended for another patient; misidentification usually as a result of mistakes made labeling the patient's blood sample sent to the blood bank or not accurately matching the unit with the patient at the time the blood is transfused. This risk is particularly high for infants because identification bands may not be attached directly to their bodies, difficulties in drawing blood samples for pretransfusion compatibility testing may lead to deviations from usual policies, and infants cannot speak to identify themselves. Thus, particular care must be taken to ensure accurate patient and blood sample identification.

Although the infectious disease risks of allogeneic blood transfusions are extremely low, transfusions must be given judiciously because "emerging infections" are a constant threat, and testing is not done for every microorganism possibly transmitted by blood transfusions (Table 474-1, Fig. 474-1). Taking nucleic acid amplification testing

Transfusion-associated cytomegalovirus (CMV) has been nearly eliminated by transfusion of leukocyte-reduced cellular blood products or by selection of blood collected from donors who are seronegative for antibody to CMV. Although it is logical to hypothesize that first collecting blood components from CMV-seronegative donors and then removing the white blood cells might further improve safety, no data are available to document the superior efficacy of this combined approach. Importantly, considerable care must be taken not to place children at risk of delayed or missed transfusions while awaiting/searching for blood from CMV-seronegative donors to, then, leukocyte-reduce (i.e., risks must not be taken for practices with no established benefits).

Another consideration is that emerging data suggest that this combined approach using CMV-seronegative blood, surprisingly, may be incorrect. Large quantities of CMV viral material are present "free" in the plasma of healthy-appearing donors during the early phase of primary infection (while CMV antibodies are either absent ["window" phase] or are newly emerging and are at low inconsistently detected levels in plasma), rather than being leukocyte-associated as occurs with CMV as substantial quantities of immunoglobulin G antibodies appear. As a result of this biology of CMV primary infection, plasma "free" CMV is plentiful during early infection. Because nearly all plasma "free" CMV disappears and becomes almost exclusively cell-associated, once donors are CMV-seropositive with antibody present for several months, it has been proposed that the best method to reduce CMV risk may be to effectively perform leukocyte reduction of blood from donors known to be CMV-seropositive for at least 1 year. However, data to prove the efficacy of this proposal are lacking, and in practice, several studies have shown that the most efficacious method currently available to prevent transfusion-transmitted CMV is to perform leukocyte-reduction in the blood center/bank without regard for the CMV-antibody status of the donor/unit (i.e., leukocyte-reduction alone performed by the blood center/bank is sufficient).

Additional infectious risks include other types of hepatitis (A, B, E) and retroviruses (human T-cell lymphotropic virus types I and II, HIV-2), syphilis, parvovirus B19, Epstein-Barr virus, human herpesvirus 8, West Nile virus, yellow fever vaccine virus, malaria, babesiosis, Anaplasmaphagocytophilum, and Chagas disease. Variant Creutzfeldt-Jacob disease has also been transmitted by blood transfusions in humans. All are reported very uncommonly, but nonetheless, provide the rationale to transfuse only when true benefits are likely.

Transfusion-associated risks of a noninfectious nature that may occur include hemolytic and nonhemolytic transfusion reactions, fluid overload, graft versus host disease, electrolyte and acid-base imbalances, iron overload if repeated transfusions are needed long term, increased susceptibility to oxidant damage, exposure to plasticizers, hemolysis with T-antigen activation of red blood cells, posttransfusion purpura, transfusion-related acute lung injury, post-transfusion immunosuppression and immunomodulation, and alloimmunization (see Table 474-1). The risk of transfusion-related acute lung injury may be reduced by reducing the use of plasma or platelets from female donors who were possibly sensitized during pregnancy or are negative for human leukocyte antigen (HLA) antibodies.

Immunologic adverse effects, including immunosuppression, immunomodulation, and alloimmunization may be reduced by leukocyte-reduction. Transfusion reactions and alloimmunization to red blood cell and leukocyte antigens seem to be uncommon in infants, perhaps because of developmental immaturity of the immune system or deficient cytokine production. When they do occur, adverse effects are seen primarily in massive transfusion settings, such as exchange.
transfusions and trauma or surgery, in which relatively large quantities of blood are needed but are rare with the small-volume transfusions usually given.

Premature infants are known to have immune dysfunction, but their relative risk of posttransfusion graft-versus-host disease is controversial. The postnatal age of the infant, the number of immunocompetent lymphocytes in the transfusion product, the degree of HLA compatibility between donor and recipient, and other poorly described phenomena determine which infants are truly at risk for graft-versus-host disease. Regardless, many centers caring for preterm infants transfuse exclusively irradiated cellular products. Directed donations with blood drawn from blood relatives must always be irradiated because of the risk of engraftment with transfused HLA-homozygous, haploidentical lymphocytes. Cellular blood products given as intrauterine and/or exchange transfusions should be irradiated, as are transfusions for patients with severe congenital immunodeficiency disorders (severe combined immunodeficiency syndrome and DiGeorge syndrome requiring heart surgery) and transfusions for recipients of hematopoietic progenitor cell transplants. Other groups who are potentially at risk but for whom no conclusive data are available include patients given T-cell antibody therapy (antithymocyte globulin or OKT3), those with organ allografts, those receiving immunosuppressive drug regimens, and those infected with HIV.

Current practice uses irradiation from a cesium, cobalt, or linear acceleration source at doses ranging from 2,500-5,000 cGy; a minimum dose of 2,500 cGy is required. All cellular blood components should be irradiated, but frozen “acellular” products, such as plasma and cryoprecipitate, do not require it. Leukocyte reduction cannot be substituted for irradiation to prevent graft versus host disease.

*Bibliography is available at Expert Consult.*
Bibliography

Hemostasis is the active process that clots blood in areas of blood vessel injury yet simultaneously limits the clot size only to the areas of injury. Over time, the clot is lysed by the fibrinolytic system, and normal blood flow is restored. If clotting is impaired, hemorrhage occurs. If clotting is excessive, thrombotic complications ensue. The hemostatic response needs to be rapid and regulated such that trauma does not trigger a systemic reaction but must initiate a rapid, localized response. Key to the speed and coordination of response is that when a platelet adheres to a site of vascular injury, the platelet surface provides a reaction surface where clotting factors bind. The active enzyme is brought together with its substrate and a catalytic cofactor on a reaction surface, accelerating reaction rates and providing activated products for reaction with clotting factors further down the coagulation cascade. Active clotting is controlled by negative feedback loops that inhibit the clotting process when the procoagulant process comes in contact with intact endothelium. The main components of the hemostatic process are the vessel wall, platelets, coagulation proteins, anticoagulant proteins, and fibrinolytic system. Most components of hemostasis are multifunctional; fibrinogen serves as the ligand between platelets during platelet aggregation and also serves as the substrate for thrombin that forms the fibrin clot. Platelets provide the reaction surface on which clotting reactions occur, form the plug at the site of vessel injury, and contract to constrict and limit clot size.

**THE PROCESS**

The intact vascular endothelium is the primary barrier against hemorrhage. The endothelial cells that line the vessel wall normally inhibit coagulation and provide a smooth surface that permits rapid blood flow.

After vascular injury, vasoconstriction occurs and flowing blood comes in contact with the subendothelial matrix (Fig. 475-1). In flowing blood, when exposed to subendothelial matrix proteins, von Willebrand factor (VWF) changes conformation and provides the glue to which the platelet VWF receptor, the glycoprotein Ib complex, binds, tethering platelets to sites of injury. When the VWF receptor binds its ligand, complex signaling occurs from the outside membrane receptor to intracellular pathways, activating the platelets and triggering secretion of storage granules containing adenosine diphosphate (ADP), serotonin, and stored plasma and platelet membrane proteins. Upon activation, the platelet receptor for fibrinogen, αIIbβ3, is switched on (“inside out” signaling) to bind fibrinogen and triggers the aggregation and recruitment of other platelets to form the platelet plug. Multiple physiologic agonists can trigger platelet activation and aggregation, including ADP, collagen, thrombin, and arachidonic acid. Aggregation involves the interaction of specific receptors on the platelet surface with plasma hemostatic proteins, primarily fibrinogen.

One of the subendothelial matrix proteins that are exposed after vascular injury is tissue factor. Just as exposed subendothelial matrix proteins bind VWF, exposed tissue factor binds to factor VII and factors X and IX and X, but that, in vitro, only the activation of factor X is measured. This is represented by the dotted line (the thrombin “tenase” complex). Factor Xa activates factor VII, it becomes unbound from von Willebrand factor, whereupon it can participate with factor IXa in the activation of factor X in the presence of phospholipid (PL) and Ca2+ (the “tenase” complex). Factor XIIa crosslinks the fibrin clot and thereby makes it more stable. Prekallikrein, high-molecular-weight kininogen (HMWK), and factor XII are shown in blue because they do not have a physiologic role in coagulation, although they contribute to the clotting time in partial thromboplastin time (PTT).

**Figure 475-1** The clotting cascade, with sequential activation and amplification of clot formation. Many of the factors (F) are activated by the clotting factors shown above them in the cascade. The activated factors are designated by the addition of an a. On the right side, the major anticoagulants and the sites that they regulate are shown: Tissue factor pathway inhibitor (TFPI) regulates tissue factor (TF); factor VIIa, protein C, and protein S (P-C/S) regulate factors VIII and V; and anti-thrombin III (AT-III) regulates factor Xa and thrombin (factor IIa). The dotted line shows that, in vivo, TF and factor VIIa activate both factors IX and X, but that, in vitro, only the activation of factor X is measured. Unactivated factor VIII, when bound to its carrier protein, von Willebrand factor, is protected from protein C inactivation. When thrombin, or factor Xa activates factor VII, it becomes unbound from von Willebrand factor, whereupon it can participate with factor IXa in the activation of factor X in the presence of phospholipid (PL) and Ca2+ (the “tenase” complex). Factor XIIa crosslinks the fibrin clot and thereby makes it more stable. Prekallikrein, high-molecular-weight kininogen (HMWK), and factor XII are shown in blue because they do not have a physiologic role in coagulation, although they contribute to the clotting time in partial thromboplastin time (PTT).
activates the clotting cascade, as shown in Figure 475-2. The activated clotting factor then initiates the activation of the next sequential clotting factor in a systematic manner. Our understanding of the sequence of steps in the cascade followed assignment of the numerals for the clotting factors for the participant proteins, and thus the sequence seems "out of numerical order." During the process of platelet activation, internalized platelet phospholipids (primarily phosphatidylserine) become externalized and interact at 2 specific, rate-limiting steps in the clotting process—those involving the cofactors factor VIII (X-ase complex) and factor V (prothrombinase complex). Both of these reactions are localized to the platelet surface and bring together the active enzyme, an activated cofactor, and the zymogen that will form the next active enzyme in the cascade. This sequence results in amplification of the process, which supplies a burst of clotting where it is physiologically needed. In vivo, autocatalysis of factor VII generates small amounts of VIIa continuously, so the system is always poised to act. Near the bottom of the cascade, the multipotent enzyme thrombin is formed. Thrombin converts fibrinogen into fibrin, activates factors V, VIII, and XI, and aggregates platelets. Activation of factor XI by thrombin amplifies further thrombin generation and contributes to inhibition of fibrinolysis. Thrombin also activates factor XIII. The stable fibrin-platelet plug is ultimately formed through clot retraction and cross linking of the fibrin clot by factor XIa.

Virtually all procoagulant proteins are balanced by an anticoagulant protein that regulates or inhibits procoagulant function. Four clinically important, naturally occurring anticoagulants regulate the extension of the clotting process: antithrombin III (AT-III), protein C, protein S, and tissue factor pathway inhibitor. AT-III is a serine protease inhibitor of the clotting process: antithrombin III (AT-III), protein C, protein S, and tissue factor pathway inhibitor. AT-III is a serine protease inhibitor that regulates factor Xa and thrombin primarily and factors IXa, XIa, and XIIa to a lesser extent. When thrombin in flowing blood encounters intact endothelium, thrombin binds to thrombomodulin, its endothelial receptor. The thrombin–thrombomodulin complex then converts protein C into activated protein C. In the presence of the cofactor protein S, activated protein C proteolyses and inactivates factor Va and factor VIIIa. Inactivated factor Va is, in fact, a functional anticoagulant that inhibits clotting. Tissue factor pathway inhibitor limits activation of factor X by factor VIIa and tissue factor and shifts the activation site of tissue factor and factor VIIa to that of factor IX (see Figs. 475-1 and 475-2).

Once a stable fibrin-platelet plug is formed, the fibrinolytic system limits its extension and also lyses the clot (fibrinolysis) to reestablish vascular integrity. Plasmin, generated from plasminogen by either urokinase-like or tissue-type plasminogen activator, degrades the fibrin clot. In the process of dissolving the fibrin clot, fibrin degradation products are produced. The fibrinolytic pathway is regulated by plasminogen activator inhibitors and α2-antiplasmin, as well as by the thrombin-activatable fibrinolytic inhibitor. Finally, the flow of blood in and around the clot is crucial, because flowing blood returns to the liver, where activated clotting factor complexes are removed and new procoagulant and anticoagulant proteins are synthesized to maintain homeostasis of the hemostatic system.

**PATHOLOGY**

Congenital deficiency of an individual procoagulant protein leads to a bleeding disorder, whereas deficiency of an anticoagulant (clotting factor inhibitor) predisposes the patient to thrombosis. In acquired hemostatic disorders, there are frequently multiple problems with homeostasis that perturb and dysregulate hemostasis. A primary illness (sepsis) and its secondary effects (shock and acidosis) activate coagulation and fibrinolysis and impair the host's ability to restore normal hemostatic function. When sepsis triggers disseminated intravascular coagulation, platelets, procoagulant clotting factors, and anticoagulant proteins are consumed, leaving the hemostatic system unbalanced and prone to bleeding or clotting. Similarly, newborn infants and patients with severe liver disease have synthetic deficiencies of both procoagulant and anticoagulant proteins. Such dysregulation causes the patient to be predisposed to both hemorrhage and thrombosis with mild or moderate triggers that result in major alterations in the hemostatic process.

In the laboratory evaluation of hemostasis, parameters are manipulated to allow assessment of isolated aspects of hemostasis and limit the multifunctionality of some of its components. The coagulation
process is studied in plasma anticoagulated with citrate to bind calcium, with added phospholipid to mimic the reaction surface normally provided by the platelet membrane and with a stimulus to trigger clotting. Calcium is added to restart the clotting process. This results in anomalies such that the in vivo physiologic pathway of clotting in which factor VIIa activates factor IX is bypassed; instead, in prothrombin time (PT), factor VIIa activates factor X. If these were truly the physiologic situation, then there would be an in vivo bypass mechanism that would ameliorate severe factor VIII and factor IX deficiencies, the 2 most common severe bleeding disorders.

475.1 Clinical and Laboratory Evaluation of Hemostasis

J. Paul Scott, Leslie J. Raffini, and Robert R. Montgomery

HISTORY
For most hemostatic disorders, the clinical history provides the most useful information. To evaluate for a bleeding disorder, the history should determine the site or sites of bleeding, the severity and duration of hemorrhage, and the age at onset. Was the bleeding spontaneous, or did it occur after trauma? Was there a previous personal or family history of similar problems? Did the symptoms correlate with the degree of injury or trauma? Does bruising occur spontaneously? Are there lumps with bruises for which there is minimal trauma? If the patient had previous surgery or significant dental procedures, was there any increased bleeding? If a child or adolescent has had surgery that affects the mucosal surfaces, such as a tonsillectomy or major dental extraction, the absence of bleeding usually rules out a hereditary bleeding disorder. Delayed or slow healing of superficial injuries may suggest a hereditary bleeding disorder. In postpubertal females, it is important to take a careful menstrual history. Because some common bleeding disorders, such as von Willebrand disease (VWD), have a fairly high prevalence, mothers and family members may have the same mild bleeding disorder and may not be cognizant that the child’s menstrual history is abnormal. Women with mild VWD who have a moderate history of bruising frequently have a reduction of that bruising during pregnancy or after administration of oral contraceptives. Some medications, such as aspirin and other nonsteroidal antiinflammatory drugs, inhibit platelet function and increase bleeding symptoms in patients with a low platelet count or abnormal hemostasis. Standardized bleeding scores have been developed and are undergoing investigation for their sensitivity and specificity in children.

Outside the neonatal period, thrombotic disorders are relatively rare until adulthood. In the neonate, physiologic deficiencies of procoagulants and anticoagulants cause the hemostatic mechanism to be dysregulated, and clinical events can lead to either hemorrhage or thrombosis. If a child or teenager presents with deep venous thrombosis or pulmonary emboli, a detailed family history must be obtained to evaluate for deep venous thrombosis, pulmonary emboli, myocardial infarction, or stroke in other family members. The presence of thrombosis, especially in the absence of a provoking agent in the child or teenager, should induce the clinician to take a careful family history and consideration of evaluation for a hereditary or acquired predisposition to thrombosis.

PHYSICAL EXAMINATION
The physical examination should focus on whether bleeding symptoms are associated primarily with the mucous membranes or skin (muco-cutaneous bleeding) or with the muscles and joints (deep bleeding). The examination should determine the presence of petechiae, ecchymoses, hematomas, hemorrhhages, or mucous membrane bleeding. Patients with defects in platelet-blood vessel wall interaction (VWD or platelet function defects) usually have mucocutaneous bleeding, which may include epistaxis, menorrhagia, petechiae, ecchymoses, occasional hematomas, and, less commonly, hematuria and gastrointestinal bleeding. Individuals with a clotting factor deficiency of factor VIII or IX (hemophilia A or B) have symptoms of deep bleeding into muscles and joints, with much more extensive ecchymoses and hematoma formation. Patients with mild VWD or other mild bleeding disorders may have no abnormal findings on physical examination. Individuals with disorders of the collagen matrix and vessel wall may have loose joints and lax skin associated with easy bruising (Ehlers-Danlos syndrome).

Patients undergoing evaluation for thrombotic disorders should be asked about swollen, warm, tender extremities or internal organs (venous thrombosis), unexplained dyspnea or persistent “pneumonia,” especially in the absence of fever (pulmonary emboli), and varicosities and postphlebitic changes. Arterial thrombi usually cause an acute, dramatic impairment of organ function, such as stroke, myocardial infarction, or a painful, white, cold extremity.

LABORATORY TESTS
In patients who have a positive bleeding history or who are actively hemorrhaging, a platelet count, PT, and partial thromboplastin time (PTT) should be performed as screening tests. In individuals with abnormal screening tests, further evaluation should be based upon those results. In a patient with an abnormal bleeding history and a positive family history, normal screening tests should not preclude further laboratory evaluation, which may include a thrombin time, VWF testing, and platelet function studies.

There are no routine screening tests for hereditary thrombotic disorders. If the family history is positive or clinical thrombosis is unexplained, specific thrombophilia assays should be performed. Thrombosis is rare in children, and when it is present, the possibility of a hereditary predisposition should be considered (see Chapter 478).

Platelet Count
Platelet count is essential in the evaluation of the child with a positive bleeding history because thrombocytopenia is the most common acquired cause of a bleeding diathesis in children. Patients with a platelet count of >50,000/mm³ rarely have significant clinical bleeding. Thrombocytosis in children is usually reactive and is not associated with bleeding or thrombotic complications. Persistent, severe thrombocytosis in the absence of an underlying illness may require evaluation for the very rare pediatric presentation of essential thrombocytethemia or polycythaemia vera.

Prothrombin Time and Activated Partial Thromboplastin Time
Because clotting factors were named in the order of discovery, they do not necessarily reflect the sequential order of activation (Table 475-1). In fact, factors III, IV, and VI were not subsequently found to be independent proteins; thus, these terms are no longer used. Only 2 factors have commonly used names: fibrinogen (factor I) and prothrombin (factor II). The dual mechanisms of activating clotting have been termed the intrinsic (surface activation) and extrinsic (tissue factor–mediated) pathways. Study of the hemostatic mechanism is further complicated in that the interactions in vivo may use different pathways from those studied in clinical laboratory testing. PT measures the activation of clotting by tissue factor (thromboplastin) in the presence of calcium. Addition of tissue factor causes a burst of factor VIIa generation. The tissue factor–factor VIIa complex activates factor X. Whether factor X is activated by the intrinsic or the extrinsic pathway, factor Xa on the platelet phospholipid surface complexes with factor V and calcium (the “prothrombinase” complex) to activate prothrombin to thrombin (also referred to as factor IIa). Once thrombin is generated, fibrinogen is converted to a fibrin clot, the end point of the reaction (see Fig. 475-2). PT is not prolonged with deficiencies of factors VIII, IX, XI, and XII. In most laboratories, the normal PT value is 10-13 sec. PT has been standardized using the international normalized ratio (INR) so that values can be compared from one laboratory or instrument to another. This ratio is used to determine similar degrees of anticoagulation with warfarin (Coumadin)–like medications.
Partial Thromboplastin Time

The intrinsic pathway involves the initial activation of factor XII, which is accelerated by 2 other plasma proteins, prekallikrein and high-molecular-weight kininogen. In the clinical laboratory, factor XII is activated using a surface (silica or glass) or a contact activator, such as ellagic acid. Factor XIIa, in turn, activates factor XI to factor XIa, which then catalyzes factor IX to factor IXa. On the platelet phospholipid surface, factor IXa complexes with factor VIII and calcium to activate factor X (“tenase” complex).

This process is accelerated by interaction with phospholipid and calcium at the steps involving factors V and VIII. An isolated deficiency of a single clotting factor may result in isolated prolongation of PT, PTT, or both, depending on the location of the factor in the clotting cascade. This approach is useful in determining hereditary clotting factor deficiencies; however, in acquired hemostatic disorders encountered in clinical practice, >1 clotting factor is frequently deficient, so the relative prolongation of PT and PTT must be assessed.

Measurement of PTT as performed in the clinical laboratory is actually “activated” PTT; however, most refer to it as PTT. This test measures the initiation of clotting at the level of factor XII through sequential steps to the final clot end point. It does not measure factor VII, factor XIII, or anticoagulants. PTT uses a contact activator (silica, kaolin, or ellagic acid) in the presence of calcium and phospholipid. Because of differences in reagents and laboratory instruments, the normal range for PTT varies among hospital laboratories. Normal ranges for PTT are much more variable from laboratory to laboratory than those for PT.

Thus, the mechanisms studied by PT and PTT allow the evaluation of clotting factor deficiencies, even though these pathways may not be the same as those occurring physiologically. In vivo, factor VIIa activates factors IX and X, but as routinely studied in the clinical laboratory, the pathway through which factor VIIa activates factor IX is not evaluated. If the tissue factor–factor VIIa complex activated only factor X, it would be difficult to explain why the most severe bleeding disorders are deficiencies of factor VIII (hemophilia A) and factor IX (hemophilia B). In vivo, thrombin is generated and feeds back to activate factor XI and accelerate the clotting process. Clotting in PTT can be prolonged by deficiencies of factor XII, prekallikrein, and high-molecular-weight kininogen, yet these deficiencies are asymptomatic conditions.

Thrombin Time

Thrombin time measures the final step in the clotting cascade, in which fibrinogen is converted to fibrin. The normal thrombin time varies between laboratories but is usually 11–15 sec. Prolongation of thrombin time occurs with reduced fibrinogen levels (hypofibrinogenemia or afibrinogenemia), with dysfunctional fibrinogen (dysfibrinogenemia), or in the presence of substances that interfere with fibrin polymerization, such as heparin and fibrin split products. If heparin contamination is a potential cause of prolonged thrombin time, a reptilase time is usually ordered. Alternatively, heparinase can be added to the sample and the thrombin time repeated.

Reptilase Time

Reptilase time uses snake venom to clot fibrinogen. Unlike thrombin time, reptilase time is not sensitive to heparin and is prolonged only by reduced or dysfunctional fibrinogen and fibrin split products. Therefore, if thrombin time is prolonged but reptilase time is normal, the prolonged thrombin time is due to heparin and does not indicate the presence of fibrin split products or reduced concentration or function of fibrinogen.

Mixing Studies

If there is unexplained prolongation of PT or PTT, a mixing study is usually performed. Normal plasma is added to the patient’s plasma, and the PT or PTT is repeated. Correction of PT or PTT by 1:1 mixing with normal plasma suggests deficiency of a clotting factor, because a 50% level of individual clotting proteins is sufficient to produce normal PT or PTT. If the clotting time is not corrected or only partially corrected, an inhibitor is usually present. An inhibitor of clotting may be either a chemical similar to heparin that delays coagulation or an antibody directed against a specific clotting factor or the phospholipid used in clotting tests. In the inpatient setting, the most common cause of this finding is heparin contamination of the sample. The presence of heparin in the sample can be ruled in or out either by addition of heparinase to the sample and repeating the thrombin time. If the mixing study is not corrected or if its result becomes more prolonged and the patient has clinical bleeding, an inhibitor of a specific clotting factor (antibody directed against the factor), most commonly factor VIII, factor IX, or factor XI, may be present. If the patient has no bleeding symptoms and both PTT and the mixing study are prolonged, a lupus-like anticoagulant (see Chapter 476) is often present. Patients with these findings usually have a long PTT, do not bleed, and may have a clinical predisposition to excessive clotting.

Bleeding Time

Bleeding time assesses the function of platelets and their interaction with the vascular wall. Dispersible standardized devices have been developed that control the length and depth of the skin incision. A blood pressure cuff is applied to the upper arm and inflated to 40 mm Hg for children and adults. In term newborns and younger children, a modified device has been developed that is used with a lower blood pressure cuff pressure. Bleeding time is a difficult laboratory test to standardize, and there is much interlaboratory and interindividual variation. Although platelet counts of <100,000/mm³ are associated with prolonged bleeding time, disproportionate prolongation of
bleeding time may suggest a qualitative platelet defect or VWD. Use of the bleeding time is declining in many centers.

**Platelet Function Analyzer**

In an attempt to evaluate the early stages of hemostasis (platelet function and VWF interaction under high shear), several in vitro platelet analyzers have been developed. The greatest experience has been with the platelet function analyzer (PFA-100, Siemens Healthcare Diagnostics, Inc., Deerfield, IL). The PFA-100 measures platelet adhesion-aggregation in whole blood at high shear when exposed to either collagen-epinephrine or collagen-ADP. Results are reported as the closure time measured in sec. The PFA-100 appears to be sensitive to severe forms of VWD and platelet dysfunction. The PFA-100 has variable sensitivity, particularly in the detection of mild VWD and some platelet function defects. Its use as a preparative screening tool has been disappointing in some studies.

**D-Dimer**

D-dimer is formed by plasmin degradation of crosslinked fibrin, produced when fibrinogen is clotted by thrombin and cross-linked by factor XIIIa and is more specific for fibrinolysis than fibrin degradation products. D-dimer is elevated in patients with disseminated intravascular coagulation or acute deep vein thrombosis but is relatively non-specific in that other ill hospitalized patients often have elevated levels of D-dimer. Adult studies show that the D-dimer can be useful to help exclude venous thrombosis and pulmonary embolus because of its high negative predictive value; for example, a patient with a normal D-dimer value is unlikely to have an acute thrombosis.

**Clotting Factor Assays**

Each of the clotting factors can be measured in the clinical laboratory using individual factor–deficient plasmas. For most clotting factors, activity is measured against pooled normal plasma or against a standard, by which 100% activity is expressed as 100 IU/dL. By definition, 1 IU of each factor is defined as that amount in 1 mL of normal plasma referenced against a standard established by the World Health Organization. For most clotting factors, the normal range is 50-150 IU/dL (50-150%) (Table 475-2).

In patients with hemophilia A or hemophilia B, inhibitors of factor VIII or factor IX may develop after exposure to replacement therapy.

All factors except fibrinogen are expressed as units/mL (fibrinogen in mg/mL), in which pooled normal plasma contains 1 unit/mL. All data are expressed as the mean, followed by the upper and lower boundaries encompassing 95% of the normal population (shown in parentheses). Normal ranges above vary based on the reagents and instruments used.

1 Levels for 19-27 wk and 28-31 wk gestation are from multiple sources and cannot be analyzed statistically.

2 Values are significantly different from those of adults.

3 Values are significantly different from those of full-term infants.

4 Value given as CTA (Committee on Thrombolytic Agents) units/mL. Normal ranges above vary based on the reagents and instruments used.

To quantitate the amount of inhibitor present, the standardized clinical assay of these clotting inhibitors is the Bethesda assay. One Bethesda unit is defined as the amount that will inhibit 50% of the clotting factor in normal plasma.

**Platelet Aggregation**

When a qualitative platelet function defect is suspected, platelet aggregation testing is usually ordered. Platelet-rich plasma from the patient is activated with 1 of a series of agonists (ADP, epinephrine, collagen, thrombin or thrombin-receptor peptide, and ristocetin). Some platelet aggregometers measure specific adenosine triphosphate release from the platelets, as reflected in generating luminescence (lumiaggregometer), and are more sensitive in detecting abnormalities of the platelet release reaction from storage granules. Repeat testing or testing of other symptomatic family members can help to determine the hereditary nature of the defect. Many medications, especially aspirin, other nonsteroidal antiinflammatory drugs, and valproic acid, alter platelet function testing. Figure 475-1 provides an approach to the differential diagnosis of many common bleeding disorders based on screening tests.

**Testing for Thrombotic Predisposition**

Hereditary predisposition to thrombosis is associated with a reduction of anticoagulant function (protein C, protein S, AT-III); the presence of a factor V molecule that is resistant to inactivation by protein C (factor V Leiden); elevated levels of procoagulants (a mutation of the prothrombin gene); or a deficiency of fibrinolysis (plasminogen deficiency); and the rare metabolic disease homocystinuria. When patients are being screened for prothrombotic tendencies, specific tests of the natural anticoagulants and polymerase chain reaction analysis for common prothrombotic mutations are warranted. Although both immunologic and functional tests are usually available, functional assays of protein C, protein S, and AT-III are clinically more useful.

**Factor V Leiden** is a common mutation in factor V that is associated with an increased risk of thrombosis. A point mutation in the factor V molecule prevents the inactivation of factor Va by activated protein C and, thereby, the persistence of factor Va. This defect, also known as *activated protein C resistance*, is easily diagnosed with DNA testing.

The *prothrombin gene mutation (G20210A)* is a mutation in the noncoding portion of the prothrombin gene, with a glycine (G) at position 20210 being replaced by an alanine (A). This mutation increases the amount of prothrombin messenger RNA, is associated with elevations of prothrombin, and causes a predisposition to thrombosis. This abnormality is easily identified with molecular diagnostic (DNA) testing.

**Elevated Homocysteine**

Levels of homocysteine may be increased as a result of genetic mutations, causing homocystinuria. Patients with homocysteine elevation are predisposed to arterial and venous thrombosis as well as to an increase in arteriosclerosis.

**Tests of the Fibrinolytic System**

Euglobulin clot lysis time is a screening test used in some laboratories to assess fibrinolysis. More specific tests are available in most laboratories to determine the levels of plasminogen, plasminogen activator, and inhibitors of fibrinolysis. An increase in fibrinolysis may be associated with hemorrhagic symptoms, and a delay in fibrinolysis is associated with thrombosis.

**DEVELOPMENTAL HEMOSTASIS**

The normal newborn infant has reduced levels of most procoagulants and anticoagulants (see Table 475-1). In general, there is a more marked abnormality in the preterm infant. Although major differences exist in the normal ranges for newborn and preterm infants, these ranges vary greatly among laboratories based upon the instruments and reagents used. During gestation, there is progressive maturation and increase of the clotting factors synthesized by the liver. The extremely premature infant has prolonged PT and PTT values as well as a marked reduction in anticoagulant protein levels (protein C, protein S, and AT-III). Levels of fibrinogen, factors V and VIII, VWF, and platelets are near-normal throughout the later stages of gestation (see Chapter 103.4). Because protein C and protein S are physiologically reduced, the normal factors V and VIII are not balanced with their regulatory proteins. In contrast, the physiologic deficiency of vitamin K–dependent procoagulant proteins (factors II, VII, IX, and X) is partially balanced by the physiologic reduction of AT-III. The net effect is that newborns (especially premature infants) are at increased risk for complications of bleeding, clotting, or both.

*Bibliography is available at Expert Consult.*
Bibliography

Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are the most common and serious congenital coagulation factor deficiencies. The clinical findings in hemophilia A and hemophilia B are virtually identical. Hemophilia C is the bleeding disorder associated with reduced levels of factor XI (see Chapter 476.2). Reduced levels of the contact factors (factor XII, high-molecular-weight kininogen, and prekallikrein) are associated with significant prolongation of activated partial thromboplastin time (aPTT; also referred to as PTT), but are not associated with hemorrhage, as discussed in Chapter 476.3. Other coagulation factor deficiencies that are less common are briefly discussed in subsequent subchapters.

476.1 Factor VIII or Factor IX Deficiency (Hemophilia A or B)

Deficiencies of factors VIII and IX are the most common severe inherited bleeding disorders. Recombinant factor VIII and factor IX concentrates are available to treat patients with hemophilia and thereby avoid the infectious risk of plasma-derived transfusion-transmitted diseases.

PATHOPHYSIOLOGY
Factors VIII and IX participate in a complex required for the activation of factor X. Together with phospholipid and calcium, they form the "tenase," or factor X-activating, complex. Figure 475-1 in Chapter 475 shows the clotting process as it occurs in the test tube, with factor X being activated by either the complex of factors VIII and IX or the complex of tissue factor and factor VII. In vivo, the complex of factor VIIa and tissue factor activates factor IX to initiate clotting. In the laboratory, prothrombin time (PT) measures the activation of factor X by factor VII and is therefore normal in patients with factor VIII or factor IX deficiency.
After injury, the initial hemostatic event is formation of the platelet plug, together with the generation of the fibrin clot that prevents further hemorrhage. In hemophilia A or B, clot formation is delayed and is not robust. Inadequate thrombin generation leads to failure to form a tightly crosslinked fibrin clot to support the platelet plug. Patients with hemophilia slowly form a soft, friable clot. When untreated bleeding occurs in a closed space, such as a joint, cessation of bleeding may be the result of tamponade. With open wounds, in which tamponade cannot occur, profuse bleeding may result in significant blood loss. The clot that is formed may be friable, and rebleeding occurs during the physiologic lysis of clots or with minimal new trauma.

**CLINICAL MANIFESTATIONS**

Neither factor VIII nor factor IX crosses the placenta; bleeding symptoms may be present from birth or may occur in the fetus. Only 2% of neonates with hemophilia sustain intracranial hemorrhages, and 30% of male infants with hemophilia bleed with circumcision. Thus, in the absence of a positive family history (hemophilia has a high rate of spontaneous mutation), hemophilia may go undiagnosed in the newborn. Obvious symptoms such as easy bruising, intramuscular hematomas, and hemarthroses begin when the child begins to cruise. Bleeding from minor traumatic lacerations of the mouth (a torn frenulum) may persist for hours or days and may cause the parents to seek medical evaluation. Even in patients with severe hemophilia, only 90% have evidence of increased bleeding by 1 yr of age. Although bleeding may occur in any area of the body, the hallmark of hemophilic bleeding is **hemarthrosis**. Bleeding into the joints may be induced by minor trauma; many hemarthroses are spontaneous. The earliest joint hemorrhages appear most commonly in the ankle. In the older child and adolescent, hemarthroses of the knees and elbows are also common. Whereas the child’s early joint hemorrhages are recognized only after major swelling and fluid accumulation in the joint space, older children are frequently able to recognize bleeding before the physician does. They complain of a warm, tingling sensation in the joint as the first sign of an early joint hemorrhage. Repeated bleeding episodes into the same joint in a patient with severe hemophilia may become a “target” joint. Recurrent bleeding may then become spontaneous because of the underlying pathologic changes in the joint.

Although most muscular hemorrhages are clinically evident owing to localized pain or swelling, bleeding into the iliopsoas muscle requires specific mention. A patient may lose large volumes of blood into the iliopsoas muscle, verging on hypovolemic shock, with only a vague area of referred pain in the groin. The hip is held in a flexed, internally rotated position owing to irritation of the iliopsoas. The diagnosis is made clinically from the inability to extend the hip but must be confirmed with ultrasonography or CT (Fig. 476-1). Life-threatening bleeding in the patient with hemophilia is caused by bleeding into vital structures (central nervous system, upper airway) or by exsanguination (external trauma, gastrointestinal or iliopsoas hemorrhage). Prompt treatment with clotting factor concentrate for these life-threatening hemorrhages is imperative. If head trauma is of sufficient concern to suggest radiologic evaluation, factor replacement should precede radiologic evaluation. Simply put: “Treat first, image second!” Life-threatening hemorrhages require replacement therapy to achieve a level equal to that of normal plasma (100 IU/dL, or 100%). Patients with mild hemophilia who have factor VIII or factor IX levels >5 IU/dL usually do not have spontaneous hemorrhages. These individuals may experience prolonged bleeding after dental work, surgery, or injuries from moderate trauma and may not be diagnosed until they are older.

**LABORATORY FINDINGS AND DIAGNOSIS**

The laboratory screening test that is affected by a reduced level of factor VIII or factor IX is PTT. In severe hemophilia, the PTT value is usually 2-3 times the upper limit of normal. Results of the other screening tests of the hemostatic mechanism (platelet count, bleeding time, prothrombin time, and thrombin time) are normal. Unless the patient has an inhibitor to factor VIII or IX, the mixing of normal plasma with patient plasma results in correction of PTT value. The specific assay for factors VIII and IX will confirm the diagnosis of hemophilia. If correction does not occur on mixing, an inhibitor may be present. In 25-35% of patients with hemophilia who receive infusions of factor VIII or factor IX, a factor-specific antibody may develop. These antibodies are directed against the active clotting site and are termed **inhibitors**. In such patients, the quantitative Bethesda assay for inhibitors should be performed to measure the antibody titer.

**DIFFERENTIAL DIAGNOSIS**

In young infants with severe bleeding manifestations, the differential diagnosis includes severe thrombocytopenia; severe platelet function...
disorders, such as Bernard-Soulier syndrome and Glanzmann thrombasthenia; type 3 (severe) von Willebrand disease; and vitamin K deficiency. Hemostatic screening tests should differentiate these entities from hemophilia.

GENETICS AND CLASSIFICATION

Hemophilia occurs in approximately 1:5,000 males, with 85% having factor VIII deficiency and 10-15% having factor IX deficiency. Hemophilia shows no apparent racial predilection, appearing in all ethnic groups. The severity of hemophilia is classified on the basis of the patient’s baseline level of factor VIII or factor IX, because factor levels usually correlate with the severity of bleeding symptoms. By definition, 1 IU of each factor is defined as that amount in 1 mL of normal plasma referenced against a standard established by the World Health Organization (WHO); thus, 100 mL of normal plasma has 100 IU/dL (100% activity) of each factor. For ease of discussion, henceforth in this chapter, we use the term % activity to refer to the percentage found in normal plasma (100% activity). Factor concentrates are also referenced against an international WHO standard, so treatment doses are usually referred to in IU. Severe hemophilia is characterized as having <1% activity of the specific clotting factor, and bleeding is often spontaneous. Patients with moderate hemophilia have factor levels of 1-5% and usually require mild trauma to induce bleeding. Individuals with mild hemophilia have levels >5%, may go many years before the condition is diagnosed, and frequently require significant trauma to cause bleeding. The hemostatic level for factor VIII is >30-40%, and for factor IX, it is >25-30%. The lower limit of levels for factors VIII and IX in normal individuals is approximately 50%.

The genes for factors VIII and IX are carried near the terminus of the long arm of the X chromosome and are therefore X-linked traits. The majority of patients with hemophilia have reduced clotting factor protein; 5-10% of those with hemophilia A and 40-50% of those with hemophilia B make a dysfunctional protein. Approximately 45-50% of patients with severe hemophilia A have the same mutation, in which there is an internal inversion within the factor VIII gene that results in production of no protein. This mutation can be detected in the blood of patients or carriers and in the amniotic fluid by molecular techniques. African-Americans often have a different factor VIII haplotype, and this difference may be the reason that African-Americans have higher inhibitor formation (see later). Because of the multiple genetic causes of either factor VIII or factor IX deficiency, most cases of hemophilia are classified according to the amount of factor VIII or factor IX clotting activity. In the newborn, factor VIII values may be artificially elevated because of the acute-phase response elicited by the birth process. This artificial elevation may cause a mildly affected patient to have normal or near-normal levels of factor VIII. Patients with severe hemophilia do not have detectable levels of factor VIII. In contrast, factor IX levels are physiologically low in the newborn. If severe hemophilia is present in the family, an undetectable level of factor IX is diagnostic of severe hemophilia B. In some patients with mild factor IX deficiency, the presence of hemophilia can be confirmed only after several weeks of life.

Through lyonization of the X chromosome, some female carriers of hemophilia A or B have sufficient reduction of factor VIII or factor IX to produce mild bleeding disorders. Levels of these factors should be determined in all known or potential carriers to assess the need for treatment in the event of surgery or clinical bleeding.

Because factor VIII is carried in plasma by von Willebrand factor, the ratio of factor VIII to von Willebrand factor is sometimes used to diagnose carriers of hemophilia. When possible, specific genetic mutations should be identified in the propositus and used to test other family members who are at risk of either having hemophilia or being carriers.

TREATMENT

Early, appropriate therapy is the hallmark of excellent hemophilia care. When mild to moderate bleeding occurs, values of factor VIII or factor IX must be raised to hemostatic levels, in the 35-50% range. For life-threatening or major hemorrhages, the dose should aim to achieve levels of 100% activity.

Calculation of the dose of recombinant factor VIII (FVIII) or recombinant factor IX (FIX) is as follows:

Dose of rFVIII (IU) = % desired (rise in FVIII) \times \text{Body weight (kg)} \times 0.5

Dose of rFIX (IU) = % desired (rise in plasma FIX) \times \text{Body weight (kg)} \times 1.4

For factor VIII, the correction factor is based on the volume of distribution of factor VIII. For factor IX, the correction factor is based on the volume of distribution and the observed rise in plasma level after infusion of recombinant factor IX.

Table 476-1 summarizes the treatment of some common types of hemorrhage in a patient with hemophilia. With the availability of recombinant replacement products, prophylaxis is the standard of care for most children with severe hemophilia, to prevent spontaneous bleeding and early joint deformities. In addition to currently available recombinant factors, products are being developed to increase the plasma half-life and reduce the immunogenicity of hemostatic factors. A study comparing prophylaxis with aggressive episodic treatment provides evidence for the superiority of prophylaxis in preventing debilitating joint disease. If target joints develop, “secondary” prophylaxis is often initiated.

With mild factor VIII hemophilia, the patient’s endogenously produced factor VIII can be released by the administration of desmopressin acetate. In patients with moderate or severe factor VIII deficiency, the stored levels of factor VIII in the body are inadequate, and desmopressin treatment is ineffective. The risk of exposing the patient with mild hemophilia to transfusion-transmitted diseases and the cost of recombinant products warrant the use of desmopressin, if it is effective. A concentrated intranasal form of desmopressin acetate, not the enuresis or pituitary replacement dose, can also be used to treat patients with mild hemophilia A. The dose is 150 μg (1 puff) for children weighing <50 kg and 300 μg (2 puffs) for children and young adults weighing >50 kg. Most centers administer a trial of desmopressin to determine the level of factor VIII achieved after its infusion. Desmopressin is not effective in the treatment of factor IX–deficient hemophilia.

Preliminary trials of an adenovirus-associated virus vector containing the factor IX gene are underway with some encouraging initial results.

PROPHYLAXIS

Many patients are now given lifelong prophylaxis to prevent spontaneous joint bleeding. The National Hemophilia Foundation recommends that prophylaxis be considered optimal therapy for children with severe hemophilia. Usually, such programs are initiated with the first joint hemorrhage. Young children often require the insertion of a central catheter to ensure venous access. Such programs are expensive but are highly effective in preventing or greatly limiting the degree of joint pathology; however, complications include central line infection and thrombosis. Treatment is usually provided every 2-3 days to maintain a measurable plasma level of clotting factor (1-2%) when assayed just before the next infusion (trough level). Whether prophylaxis should be continued into adulthood has not yet been adequately studied. If moderate arthropathy develops, prevention of future bleeding will require higher plasma levels of clotting factors. In the older child who is not given primary prophylaxis, secondary prophylaxis is frequently initiated if a target joint develops.

SUPPORTIVE CARE

Although it is easy to tell parents that their child should avoid trauma, this advice is not practical in active children and adolescents. Toddlers are active, are curious about everything, and injure themselves easily. Effective measures include anticipatory guidance, including the use of car seats, seatbelts, and bike helmets, and the importance of avoiding high-risk behaviors. Older boys should be counseled to avoid violent contact sports, but this issue is a challenge. Boys with severe hemophilia often sustain hemorrhages in the absence of known trauma. Early psychosocial intervention helps the family achieve a balance
between overprotection and permissiveness. Patients with hemophilia should avoid aspirin and other nonsteroidal antiinflammatory drugs that affect platelet function. The child with a bleeding disorder should receive the appropriate vaccinations against hepatitis B, although recombinant products may avoid exposure to transfusion-transmitted diseases. Patients exposed to plasma-derived products should be screened periodically for hepatitis B and C, HIV, and abnormalities in liver function.

**CHRONIC COMPLICATIONS**

Long-term complications of hemophilia A and B include chronic arthropathy, the development of an inhibitor to either factor VIII or factor IX, and the risk of transfusion-transmitted infectious diseases. Although an aggressive, or prophylactic, approach to treatment has reduced the problems of chronic arthropathy, these problems have not been eliminated.

Historically, chronic arthropathy has been the major long-term disability associated with hemophilia. The natural history of untreated hemophilia is one of cyclic recurrent hemorrhages into specific joints, including hemarthroses into the same (target) joint. In young children, the joint distends easily and a large volume of blood may fill the joint until tamponade ensues or therapy intervenes. After joint hemorrhage, proteolytic enzymes are released by white blood cells into the joint space, and heme iron induces macrophage proliferation, leading to inflammation of the synovium. The synovium thickens and develops frondlike projections into the joint that are susceptible to being pinched and may induce further hemorrhage. The cartilaginous surface becomes eroded and ultimately may even expose raw bone, leaving the joint susceptible to articular fusion. In the older patient with advanced arthropathy, bleeding into the target joint, with its thickened synovium, causes severe pain, because the joint may have little space to accommodate blood. Once a target joint is seen to be developing, the patient is usually given short- or long-term prophylaxis to prevent progression of the arthropathy and reduce inflammation.

**Inhibitor Formation**

Infusion of the deficient clotting factor may initiate an immune response in patients with either factor VIII or factor IX deficiency. Inhibitors are antibodies directed against factor VIII or factor IX that block the clotting activity. Failure of a bleeding episode to respond to appropriate replacement therapy is usually the first sign of an inhibitor. Less often, inhibitors are identified during routine follow-up screening for inhibitors. Inhibitors develop in approximately 25-35% of patients with hemophilia A; the percentage is somewhat lower in patients with hemophilia B, many of whom make an inactive dysfunctional protein with hemophilia A; the percentage is somewhat lower in patients with hemophilia B. Inhibitors are antibodies directed against factor VIII or factor IX that affect platelet function. The child with a bleeding disorder should receive the appropriate vaccinations against hepatitis B, although recombinant products may avoid exposure to transfusion-transmitted diseases. Patients exposed to plasma-derived products should be screened periodically for hepatitis B and C, HIV, and abnormalities in liver function.

*For hip hemorrhage, orthopedic evaluation for possible aspiration is advisable to prevent avascular necrosis of the femoral head.
†For mild or moderate hemophilia, desmopressin, 0.3 µg/kg, should be used instead of factor VIII concentrate, if the patient is known to respond with a hemostatic level of factor VII; if repeated doses are given, monitor factor VIII levels for tachyphylaxis.
‡Stated doses apply for recombinant factor IX concentrate; for plasma-derived factor IX concentrate, use 70% of the stated dose.
§Do not give antifibrinolytic therapy until 4-6 hr after a dose of prothrombin complex concentrate.
**Repeat radiologic assessment should be performed before discontinuation of therapy.
††If repeated doses of factor IX concentrate are required, use highly purified, specific factor IX concentrate.
off-label (i.e., in a use not approved by the FDA), as an alternate therapy for patients with high inhibitor titers in whom immune tolerance programs have failed. Some centers first begin with prednisone with or without cyclophosphamide; others add cyclosporine if there is a poor response. If desensitization fails, bleeding episodes are treated with either recombinant factor VIIa or activated prothrombin complex concentrates (factor VIII inhibitor bypassing activity). The use of these products bypasses the inhibitor in many instances but may increase the risk of thrombosis. Some patients with low titers of inhibitor can be treated with high-dose factor VIII during a bleeding episode. Patients with inhibitors require referral to a center that cares for many such patients and has a comprehensive hemophilia program.

In the past, plasma-derived treatment products transmitted hepatitis B and C as well as HIV to large numbers of patients with hemophilia. In the era of recombinant products, the risk of acquiring such infections should be minimal, but patients should receive appropriate immunizations against hepatitis B. Those who are exposed to blood products should be monitored for transfusion-related infections. Reports have also identified the transmission of variant Creutzfeldt-Jakob disease to patients receiving therapeutic plasma and may warrant study of patients with hemophilia for prion transmission from plasma-derived factor concentrates.

**COMPREHENSIVE CARE**

Patients with hemophilia are best managed through comprehensive hemophilia care centers. Such centers are dedicated to patient and family education as well as to the prevention and/or treatment of the complications of hemophilia, including chronic joint disease and inhibitor development as well as infection, such as hepatitis B and C or HIV. Such centers involve a team of physicians, nurses, orthopedists, physical therapists, and psychosocial workers, among others. Education remains crucial in hemophilia care, because patients who are receiving prophylaxis may be less “experienced” in recognizing bleeding episodes than affected children from previous eras.

Bibliography is available at Expert Consult.

### 476.2 Factor XI Deficiency (Hemophilia C)

**J. Paul Scott**

Factor XI deficiency is an autosomal deficiency associated with mild to moderate bleeding symptoms. It is frequently encountered in Ashkenazi Jews but has been found in many other ethnic groups. In Israel, 1-3/1,000 individuals are homozygous for this deficiency.

The bleeding tendency is not as severe as in factor VIII or factor IX deficiency. The bleeding associated with factor XI deficiency is not correlated with the amount of factor XI. Some patients with severe deficiency may have minimal or no symptoms at the time of major surgery. Because factor XI augments thrombin generation and leads to activation of the fibrinolytic inhibitor thrombin-activatable fibrinolysis inhibitor, surgical bleeding is more prominent in sites of high fibrinolytic activity like the oral cavity. Unless the patient previously had surgery without bleeding, replacement therapy should be considered and given preoperatively, depending on the nature of the surgical procedure. No approved concentrate of factor XI is available in the United States; therefore, the physician must use fresh-frozen plasma (FFP).

Bleeding during minor surgery can be controlled with local pressure. Patients undergoing dental extractions can be monitored closely and may benefit from treatment with fibrinolytic inhibitors like aminoproic acid, with plasma replacement therapy used only if hemorrhage occurs. In a patient with homozygous deficiency of factor XI, PTT is often longer than it is in patients with either severe factor VIII or factor IX deficiency. The paradox of fewer clinical symptoms in combination with longer PTT is surprising, but it occurs because factor VIIa can activate factor IX in vivo. The deficiency of factor XI can be confirmed by specific factor XI assays. Plasma infusions of 1 IU/kg usually increase the plasma concentration by 2%. Thus, infusion of plasma at 10-15 mL/kg will result in a plasma level of 20-30%, which is usually sufficient to control moderate hemorrhage. Frequent infusions of plasma would be necessary to achieve higher levels of factor XI. Because the half-life of factor XI is usually ≥48 hr, maintaining adequate levels of factor XI commonly is not difficult.

Chronic joint bleeding is rarely a problem in factor XI deficiency, and for most patients, the deficiency is a concern only at the time of major surgery unless there is a second underlying hemostatic defect (e.g., von Willebrand disease).

Bibliography is available at Expert Consult.

### 476.3 Deficiencies of the Contact Factors (Nonbleeding Disorders)

**J. Paul Scott**

Deficiency of the “contact factors” (factor XII, prekallikrein, and high-molecular-weight kininogen) causes prolonged PTT but no bleeding symptoms. Because these contact factors function at the step of initiation of the intrinsic clotting system by the reagent used to determine PTT, the PTT is markedly prolonged when these factors are absent. Thus, there is the paradoxical situation in which PTT is extremely prolonged with no evidence of clinical bleeding. It is important that individuals with these findings be well informed about the meaning of their clotting factor deficiency because they do not need treatment, even for major surgery.

### 476.4 Factor VII Deficiency

**J. Paul Scott**

Factor VII deficiency is a rare autosomal bleeding disorder that is usually detected only in the homozygous state. Severity of bleeding varies from mild to severe with hemorrhathrosis, spontaneous intracranial hemorrhage, and mucocutaneous bleeding, especially nosebleeds and menorrhagia. Patients with this deficiency have markedly prolonged PT but normal PTT. Factor VII assays show a marked reduction in factor VII. Because the plasma half-life of factor VII is 2-4 hr, therapy with FFP is difficult and is often complicated by fluid overload. A commercial concentrate of recombinant factor VIIa is effective in treating patients with factor VII deficiency.

Bibliography is available at Expert Consult.

### 476.5 Factor X Deficiency

**J. Paul Scott**

Factor X deficiency is a rare (estimated 1/1,000,000) autosomal disorder with variable severity. Mild deficiency results in mucocutaneous and posttraumatic bleeding, whereas severe deficiency results in spontaneous hemorrhathrosis and intracranial hemorrhages. Factor X deficiency is the result of either a quantitative deficiency or a dysfunctional molecule. A reduced factor X level is associated with prolongation of both PT and PTT. In patients with hereditary factor X deficiency, factor X levels can be increased with use of either FFP or prothrombin complex concentrate. The half-life of factor X is approximately 30 hr, and its volume of distribution is similar to that of factor IX. Thus, 1 unit/kg will increase the plasma level of factor X by 1%.

Although it is rarely a problem in pediatric patients, systemic amyloidosis may be associated with factor X deficiency, owing to the adsorption of factor X on the amyloid protein. In the setting of amyloidosis, transfusion therapy often is not successful because of the rapid clearance of factor X.

476.6 Prothrombin (Factor II) Deficiency
J. Paul Scott

Prothrombin deficiency is caused either by a markedly reduced prothrombin level (hypoprothrombinemia) or by functionally abnormal prothrombin (dysprothrombinemia). Laboratory testing in homozygous patients shows prolonged PT and PTT. Factor II, or prothrombin, assays show a markedly reduced prothrombin level. Mucocutaneous bleeding in infancy and posttraumatic bleeding later are common. Patients are treated with either FFP or, rarely, prothrombin concentrate. In prothrombin deficiency, FFP is useful, because the half-life of prothrombin is 3.5 days. Administration of 1 IU/kg of prothrombin will increase the plasma activity by 1%.

Bibliography is available at Expert Consult.

476.7 Factor V Deficiency
J. Paul Scott

Deficiency of factor V is an autosomal recessive, mild to moderate bleeding disorder that has also been termed parahemophilia. Hemarthroses occur rarely; mucocutaneous bleeding and hematomas are the most common symptoms. Severe menorrhagia is a frequent symptom in women. Laboratory evaluation shows prolonged PTT and PT. Specific assays for factor V show a reduction in factor V levels. FFP is the only currently available therapeutic product that contains factor V. Factor V is lost rapidly from stored FFP. Patients with severe factor V deficiency are treated with infusions of FFP at 10 mL/kg every 12 hr. Rarely, a patient with a negative family history of bleeding has an acquired antibody to factor V. Often, such a patient does not bleed because the factor V in platelets prevents excessive bleeding.

Bibliography is available at Expert Consult.

476.8 Combined Deficiency of Factors V and VIII
J. Paul Scott

Combined deficiency of factors V and VIII occurs secondary to the absence of an intracellular transport protein that is responsible for transporting factors V and VIII from the endoplasmic reticulum to the Golgi compartments. This explains the paradoxical deficiency of 2 factors, one encoded on chromosome 1 and the other on the X chromosome. Bleeding symptoms are often milder than for hemophilia A and are treated with FFP to replace both factors V and VIII.

476.9 Fibrinogen (Factor I) Deficiency
J. Paul Scott

Congenital afibrinogenemia is a rare autosomal recessive disorder in which there is an absence of fibrinogen. Patients with this disorder do not bleed as frequently as patients with hemophilia and rarely have hemarthroses. Affected patients may present in the neonatal period with gastrointestinal hemorrhage or hematomas after vaginal delivery. In addition to marked prolongation of PT and PTT, thrombin time is prolonged. In the absence of consumptive coagulopathy, an unmeasur-

able fibrinogen level is diagnostic. In addition to the quantitative deficiency of fibrinogen, a number of dysfunctional fibrinogens have been reported (dysfibrinogenemia). Rarely patients with dysfibrinogenemia present with thrombosis. A human fibrinogen concentrate is commercially available for therapy of bleeding episodes in afibrinogenemic patients. Because the plasma half-life of fibrinogen is 2-4 days, treatment with either FFP or cryoprecipitate is also effective. The hemostatic level of fibrinogen is >60 mg/dL. Each bag of cryoprecipitate contains 100-150 mg of fibrinogen. Some clinical assays for fibrinogen are inhibited by high doses of heparin. Thus, a markedly prolonged thrombin time associated with a low fibrinogen level should be evaluated with determination of reptilase time. Prolonged reptilase time confirms that functional levels of fibrinogen are low and that heparin is not present.

Bibliography is available at Expert Consult.

476.10 Factor XIII Deficiency
(Fibrin-Stabilizing Factor or Transglutaminase Deficiency)
J. Paul Scott

Because factor XIII is responsible for the crosslinking of fibrin to stabilize the fibrin clot, symptoms of delayed hemorrhage are secondary to instability of the clot. Typically, patients have trauma 1 day and then have a bruise or hematoa the next day. Clinical symptoms include mild bruising, delayed separation of the umbilical stump beyond 4 wk in neonates, poor wound healing, and recurrent spontaneous abortions in women. Rare kindreds with XIII deficiency have hemarthroses and intracranial hemorrhage have been described. Results of the usual screening tests for hemostasis are normal in patients with factor XIII deficiency. Screening tests for factor XIII deficiency are based on the observation that there is increased solubility of the clot because of the failure of crosslinking. The normal clot remains insoluble in the presence of 5M urea, whereas in a patient with XIII deficiency, the clot dissolves. More specific assays for factor XIII are immunologic. The half-life of factor XIII is 5-7 days and the hemostatic level is 2-3% activity. There is a heat-treated, lyophilized concentrate of coagulation factor XIII available to treat bleeding episodes or for prophylaxis.

476.11 Antiplasmin or Plasminogen Activator Inhibitor Deficiency
J. Paul Scott

Deficiency of either antiplasmin or plasminogen activator inhibitor, both of which are antifibrinolytic proteins, results in increased plasmin generation and premature lysis of fibrin clots. Affected patients have a mild bleeding disorder characterized by mucocutaneous bleeding but rarely have joint hemorrhages. Because results of the usual hemostatic tests are normal, further work-up of a patient with a positive bleeding history should include euglobulin clot lysis time (if available), which measures fibrinolytic activity and yields a shortened result in the presence of these deficiencies. Specific assays for α2-antiplasmin and plasminogen activator inhibitor are available. Bleeding episodes are treated with FFP; bleeding in the oral cavity may respond toaminocaproic acid.

Chapter 476  Hereditary Clotting Factor Deficiencies (Bleeding Disorders)  2389.e3

**Bibliography**

Bibliography
von Willebrand disease (VWD) is the most common inherited bleeding disorder, with an estimated prevalence cited at 1:100 to 1:10,000 depending on the criteria used for diagnosis. Patients with VWD typically present with mucosal bleeding. A family history of either VWD or bleeding symptoms and confirmatory laboratory testing are also required for the diagnosis of VWD.

**PATHOPHYSIOLOGY**

VWD is caused by a defect in von Willebrand factor (VWF). VWF has several functions in coagulation. First, VWF serves to tether platelets to injured subendothelium via binding sites for platelets and for collagen. Second, VWF serves as a carrier protein for factor VIII (FVIII), protecting FVIII from degradation in plasma. VWF is stored in endothelial cells and in platelet Weibel-Palade bodies and circulates as a large multimeric glycoprotein. Shear stress induces a conformational change in VWF that facilitates its ability to bind platelets through a binding site on platelet glycoprotein Ib (GPIb). This enables VWF to recruit platelets to the site of clot formation, a function that is dependent on the high-molecular-weight multimer forms of VWF.

VWD typically presents with mucosal bleeding, similar to that seen with other platelet defects. Epistaxis, easy bruising, and menorrhagia in women are common complaints. Symptoms, however, are variable, and do not necessarily correlate well with VWF levels. Surgical bleeding, particularly with dental extractions or adenotonsillectomy, is another common presentation. Severe type 3 VWD may present with joint bleeds. Most patients will have a family history of bleeding. Women are more likely to be diagnosed with VWD because of the potential for symptoms with menorrhagia, but men and women are equally likely to have VWD. Diagnosis based on symptoms may be difficult, however, as minor bruising and epistaxis are not uncommon in childhood. Significant unexplained bruising is more often from nonaccidental trauma than from an underlying bleeding disorder.

**CLASSIFICATION**

VWD may be caused by quantitative or qualitative defects in VWF. Mild to moderate quantitative defects are classified as type 1 VWD, while severe quantitative defects, in which there is no detectable VWF protein, are classified as type 3 VWD. The qualitative defects are grouped together as type 2 VWD.

Type 1 VWD is by far the most common type, accounting for 60-80% of all VWD patients. Typical symptoms include mucosal bleeding, such as epistaxis and menorrhagia as well as easy bruising and potentially surgical bleeding. Guidelines from the National Heart, Lung, and Blood Institute of the National Institutes of Health use a VWF level, as measured by the VWF antigen assay (VWF:Ag), of <30 IU/dL for diagnosis of VWD. Patients with VWF:Ag <20-30 IU/dL are most likely to have a genetic defect in VWF. Patients with VWF:Ag between 30 and 50 IU/dL are said to have "low VWF." Whether or not this category truly represents VWD is a subject of some debate. Because some patients with VWF levels in this range do experience bleeding, many physicians elect to treat them, especially for surgeries such as tonsillectomy.

Patients with low VWF may have VWD as a result of increased clearance of their VWF, or type 1C VWD. Diagnosis of this subtype is important because treatment of these patients with desmopressin is likely to be ineffective, necessitating administration of VWF-containing products.

VWF levels can be influenced by external factors. Blood type has long been known to affect VWF, with lower VWF levels seen in people with blood group O. Stress, exercise, and pregnancy all increase VWF levels; therefore, a single normal VWF level does not necessarily rule out the presence of VWD. Certain diseases, such as hypothyroidism, and medications, such as valproic acid, can lower VWF levels in affected patients. Repeat testing may be required to rule out or confirm a diagnosis of VWD.

Type 3 VWD is the most severe form and presents with symptoms similar to those seen in mild hemophilia. In type 3 VWD, the VWF protein is completely absent. Type 3 VWD is seen at a frequency of approximately 1 in 1,000,000. In addition to mucosal bleeding, patients may experience joint bleeds or central nervous system hemorrhage. Some physicians elect to treat patients with prophylaxis, or modified prophylaxis following injury, given that these patients typically have very low FVIII (<10 IU/dL). Because type 3 VWD is caused by a lack of VWF, treatment with VWF-containing concentrates is required.

Type 2A VWD is characterized by a defect in VWF multimerization and decreased VWF activity in terms of platelet binding. It is the most common of the type 2 variants, accounting for approximately 10% of VWD cases. Type 2A VWD can result from mutations that affect multimer assembly and processing, or mutations that result in increased proteolysis of secreted VWF. Some mutations affect both secretion and clearance of the VWF. Regardless of the mechanism, all type 2A VWD patients lack the high-molecular-weight multimers, and therefore have reduced VWF activity which results in bleeding. Symptoms are typically more severe than those seen in type 1 VWD. Desmopressin may have clinical efficacy for treatment of minor bleeding, but significant surgical challenges or major bleeding symptoms generally require a VWF-containing concentrate for treatment.

Type 2B VWD results from gain-of-function mutations that increase the activity of VWF to bind platelets. This leads to increased clearance of both VWF and platelets from circulation and results in the loss of high-molecular-weight multimers and decreased VWF activity, similar to that seen in type 2A VWD. Special testing is, therefore, required to diagnose type 2B VWD, either by direct measurement of the increased platelet binding or by an increased response to low-dose ristocetin on platelet aggregation testing. Thrombocytopenia is not always present and may be more prominent during times of stress such as surgery or pregnancy. Desmopressin is relatively contraindicated in type 2B VWD as it may accelerate VWF-platelet binding and clearance.

Platelet-type, pseudo-VWD occurs when a mutation in platelet GPIb causes spontaneous binding to VWF and also presents with decreased VWF activity, loss of high-molecular-weight multimers, and thrombocytopenia similar to type 2B VWD. Specific testing is required to distinguish the 2 conditions. Because the defect involves platelets, treatment generally requires platelet transfusion.

Type 2M VWD includes those patients with decreased VWF activity but normal (or near-normal) multimer distribution. This is generally caused by a defect in the ability of VWF to bind platelet GPIb, but this category also includes patients with defects in VWF-collagen interactions. Some minor bleeding in type 2M VWD may respond to desmopressin, but because type 2M VWD is a functional defect, treatment with VWF-containing concentrates is usually required.

Type 2N VWD is characterized by a defect in the ability of VWF to bind platelet GPIb causes spontaneous binding to VWF and also presents with decreased VWF activity, loss of high-molecular-weight multimers, and thrombocytopenia similar to type 2B VWD. Specific testing is required to distinguish the 2 conditions. Because the defect involves platelets, treatment generally requires platelet transfusion.

Type 2N VWD is characterized by a defect in the ability of VWF to bind platelet GPIb. Some patients with type 2N VWD may be misdiagnosed as mild hemophilia, therefore a high index of suspicion for this diagnosis is required in patients with low FVIII and an absent family history of FVIII deficiency.

**LABORATORY DIAGNOSIS**

There are no reliable screening tests for VWD. Patients with significant bleeding may present with anemia, and some patients with type 2B VWD or platelet-type, pseudo-VWD may have thrombocytopenia. The partial thromboplastin time may be prolonged if FVIII is low, but especially in mild type 1 VWD it is often normal, precluding use of the partial thromboplastin time as a screening test. Platelet function analysis has been considered as a screening test for VWD, but suboptimal
sensitivity and specificity render results difficult to interpret. Bleeding times are similarly unreliable in diagnosis of VWD.

Unfortunately there is no single test that can reliably diagnose VWD. Therefore a panel of tests is usually required. Table 477-1 lists the laboratory tests commonly used in diagnosis of VWD. These include VWF antigen (VWF:Ag), which measures the total amount of VWF protein present, and VWF activity, which is typically performed using the ristocetin cofactor activity assay (VWF:RCo) and provides a measure of the amount of functional VWF. FVIII activity is also usually included in the workup. Another important test is the VWF multimer distribution, although this is not routinely performed by all laboratories. Table 477-2 summarizes the expected laboratory findings for each type of VWD. Figure 477-1 provides more detailed analysis.

Additional specialized testing may be employed to help ascertain the correct diagnosis. Specific testing for type 1C (clearance defects), type 2B, and type 2N VWD can confirm these diagnoses. Genetic diagnosis is not typically performed, partly as a result of the large size of the VWF gene and the large number of benign sequence variations. Large gene deletions are responsible for some cases of VWD and will not be picked up on routine DNA sequencing. Use of genetic diagnosis is increasing, however, particularly for types 2A, 2B, 2M, and 2N VWD.

**TREATMENT**

Treatment of VWD depends on the type of VWD present and on the reason for treatment. Table 477-3 outlines the options for treatment. In general, type 1 VWD patients may be treated with desmopressin, which increases the amount of circulating VWF by release from storage. The exceptions are the rare type 1 patient who lacks a response to desmopressin, and patients with type 1C VWD who do respond with an increase in VWF levels, but whose rapid clearance of circulating endogenous VWF results in a rapid return to baseline levels. Treatment of types 2 and 3 VWD requires VWF-containing concentrates similar to the treatment of hemophilia. Dosing depends on the type of VWD, and reason for treatment. Careful monitoring of VWF and FVIII levels is recommended to tailor treatment for surgeries and major trauma. For all types of VWD, adjunct therapy should be
considered when possible, such as the use of antifibrinolytics for oral surgery or hormonal treatment for menorrhagia. Alternate treatment strategies should also be considered, particularly for difficult symptoms or severe VWD. Hormonal therapy for women with menorrhagia, although not specific to VWD, can be very helpful in managing symptoms and improving quality of life. Local treatment of epistaxis, such as nasal cautery or packing, may be helpful in some circumstances. Iron therapy for patients with iron-deficiency anemia may also be required.

Bibliography
Pediatricians are frequently asked to evaluate children for inherited risk factors for thrombosis with symptomatic thrombosis or asymptomatic children who have relatives affected with either thrombosis or thrombophilia. The clinical utility of thrombophilia testing is debated, both in adults and children.

Thrombophilia testing rarely influences the acute management of a child with a thrombotic event. The association between inherited thrombophilia and pediatric thrombosis varies based on the clinical scenario: children with unprovoked thrombotic events have a high prevalence of inherited defects, while the role of thrombophilic defects in children with catheter-related thrombotic events is questionable. Although some thrombophilic defects are associated with a higher risk of recurrent venous thromboembolism in children, how to use these results to guide the duration of therapy has not been determined. Prospective longitudinal analyses of such patients to determine outcome and response to treatment as well as the impact of known thrombophilic states on these outcomes are clearly needed.

The decision to perform thrombophilia testing in an otherwise healthy child with a family history of thrombosis or thrombophilia should be carefully considered, weighing the potential advantages and limitations of such an approach. Given that the absolute risk of thrombosis in children is extremely low (0.07/100,000), it is unlikely that an inherited thrombophilia will have any impact on clinical decision-making for a young child. The risk of thrombosis increases with age, so identification of a thrombophilic defect in an adolescent may guide thromboprophylaxis in high-risk situations (lower extremity casting or prolonged immobility), inform the discussion about estrogen-based contraceptives, and promote lifestyle modification to avoid behavioral prothrombotic risk factors (sedentary lifestyle, dehydration, obesity, and smoking). Limitations of such testing include the cost as well as the potential for causing unnecessary anxiety or false reassurance.

Table 478-1 lists the most common inherited thrombophilias and their prevalence in the general population. The inherited defects in which the pathogenic link is best understood include the factor V Leiden mutation, the prothrombin gene mutation, and deficiencies of
protein C, protein S, and antithrombin (AT). Elevated levels of factor VIII and homocysteine are associated with thrombosis, though these are less-well characterized and not necessarily genetically determined. Although there are additional alterations in coagulation that have been associated with thrombotic risk, including elevated concentrations of factors IX and XI, hepatic cofactor II deficiency, elevated lipoprotein (a), and dysfibrinogenemia, none has gained widespread acceptance in routine testing of children for inherited thrombophilia.

The factor V Leiden mutation is the result of a single nucleotide change at nucleotide 1765 within the factor V gene. This mutation causes factor Va to become resistant to inactivation by activated protein C and is the most common inherited risk factor for thrombosis. This defect is also known as activated protein C resistance. Approximately 5% of the U.S. white population is heterozygous for this mutation, and it is less prevalent in other ethnic groups. Individuals who are heterozygous have a 5–7-fold increase in risk of venous thrombosis, while homozygotes have a relative risk of 80–100. The baseline annual risk of thrombosis for young women of reproductive age is 1 per 12,500 and increases to 1 per 3,500 for those on oral contraceptives. For young women who are heterozygous for the factor V Leiden mutation and are taking oral contraceptives, this baseline annual risk is increased 20–30-fold (relative risk) to approximately 1 per 500 women.

The prothrombin 20210 gene mutation is a G-to-A transition in the 3’ untranslated region of the gene that results in increased levels of prothrombin messenger RNA. This variant is present in approximately 2% of U.S. whites. It is a weaker risk factor for venous thrombosis than factor V Leiden, with a relative risk of 2–3.

Deficiencies of protein C, protein S, and AT, the natural anticoagulant proteins, are more rare than the common genetic mutations described previously but are associated with a stronger risk of thrombosis. Although heterogeneous deficiencies do not often present during childhood, homozygous defects may result in significant symptoms in infancy. Neonates with homozygous deficiencies of AT, protein C, or protein S may present with purpuric fulminans. This condition is characterized by rapidly spreading purpuric skin lesions resulting from thromboses of the small dermal vessels followed by bleeding into the skin. In addition, these infants may also develop cerebral thrombosis, ophthalmic thrombosis, disseminated intravascular coagulation, and large vessel thrombosis. An infant with purpuric skin lesions of unknown cause should receive initial replacement with fresh-frozen plasma. Definitive diagnosis can be difficult in the sick premature neonate who may have undetectable levels of these factors but not have a true genetic deficiency. Protein C and AT concentrations are also available and have been demonstrated to be effective.

Both venous and arterial thromboses are common in young patients with homocystinuria, an inborn error of metabolism caused by deficiency of cystathionine β-synthase. In this very rare condition, plasma levels of homocysteine exceed 100 µmol/L. Much more common are mild to moderate elevations of homocysteine, which may be acquired or associated with a polymorphism in the methylenetetrahydrofolate reductase (MTHFR) gene. Although moderate elevations of homocysteine have been associated with both venous and arterial thrombotic events, testing for polymorphisms in the MTHFR gene are not indicated, because these polymorphisms are not associated with thrombophilia. The pathogenic mechanisms for thrombosis in homocysteinemia are not well understood.

Increased plasma concentrations of factor VIII (>150 IU/dl) appear to be regulated by both genetic and environmental factors and are associated with an increased risk of thrombosis. Although there is a strong component of heritability contributing to factor VIII levels, the molecular mechanisms responsible for elevated factor VIII are not well understood. Factor VIII is also considered to be an acute-phase reactant, and may increase transiently during periods of inflammation.

Although interpretation of genetic studies (Factor V Leiden and Prothrombin gene mutations) are fairly straightforward, there are several challenges in interpretation of thrombophilia studies that are unique to pediatric patients. Neonates have decreased concentrations of protein C, protein S, and AT that increase rapidly over the first 6 mo of life; protein C concentrations remain below adult levels throughout much of childhood. It is important to use pediatric normal ranges when evaluating these values, and recognize that often the normal range overlaps with heterozygous defects and retesting may be required, particularly in young children. There are several nongenetic factors that may also influence the results of inherited thrombophilia testing, including acute thrombosis, infection, inflammation, hepatic dysfunction, nephrotic syndrome, medication and vitamin K deficiency. In some cases, the hereditary nature may be confirmed by testing the parents.

Bibliography
Compared to adults, children are generally protected from venous and arterial thromboses. Advancements in the treatment and supportive care of critically ill children, coupled with a heightened awareness of genetic risk factors for thrombosis, have led to an increase in the diagnosis of thromboembolic events (TEs) in children. As a result, TEs are not infrequent in pediatric tertiary care centers and may result in significant acute and chronic morbidity. Despite the fact that TEs in children are increasing in relative terms, they are still rare. This rarity has been the major impediment to prospective clinical trials, resulting in a deficit of evidence-based medicine. Diagnosis and treatment is often extrapolated from adult data.

**EPIDEMIOLOGY**

Studies have confirmed a significant increase in the diagnosis of venous thromboembolism (VTE) in pediatric tertiary hospitals across the United States. Although the overall incidence of thrombosis in the general pediatric population is quite low (0.07/100,000), the rate of VTE in hospitalized children is 60/10,000 admissions. Infants <1 yr old account for the largest proportion of pediatric VTEs, with a second peak during adolescence.

The majority of children who develop a TE have multiple risk factors that may be acquired, inherited, and/or anatomic (Table 479-1). The presence of a central venous catheter (CVC and peripherally inserted central venous catheter) is the single most important risk factor for VTE in pediatric patients, associated with approximately 90% of neonatal VTE and 60% of childhood VTE. These catheters are often necessary for the care of premature neonates and children with acute and chronic diseases and are used for intravenous hyperalimentation, chemotherapy, dialysis, antibiotics, or supportive therapy. CVCs may damage the endothelial lining and/or cause blood flow disruption, increasing the risk of thrombosis. There are multiple other acquired risk factors that are associated with thrombosis, including trauma, infection, chronic medical illnesses, and medications. Cancer, congenital heart disease, and prematurity are the most common medical conditions associated with TEs.

Antiphospholipid antibody syndrome (APS) is a well-described syndrome in adults characterized by recurrent fetal loss and/or thrombosis. Antiphospholipid antibodies are associated with both venous and arterial thrombosis. The mechanism by which these antibodies cause thrombosis is not well understood. A diagnosis of APS requires the presence of both clinical and laboratory abnormalities (see “Laboratory Testing” below). The laboratory abnormalities must be persistent for 12 wk. Because of the high risk of recurrence, patients with APS often require long-term anticoagulation. It is important to note that healthy children may have a transient lupus anticoagulant, often diagnosed because of a prolonged partial thromboplastin time on routine preoperative testing. These antibodies may be associated with a recent viral infection and are not a risk factor for thrombosis.

Anatomic abnormalities that impede blood flow also predispose patients to thrombosis at an earlier age. Atresia of the inferior vena cava has been described in association with acute and chronic lower extremity deep venous thrombosis (DVT). May-Thurner syndrome (compression of the left iliac vein by the overlying right iliac artery) should be considered in patients who present spontaneously with left iliofemoral thrombosis, and thoracic outlet obstruction (Paget-

Schroetter syndrome) frequently presents with effort-related axillary-subclavian vein thrombosis.

**CLINICAL MANIFESTATIONS**

**Extremity Deep Vein Thrombosis**

Children with acute DVT often present with extremity pain, swelling, and discoloration. A history of a current or recent CVC in that extremity should be very suggestive. Many times, symptoms of CVC-associated thrombosis are more subtle and chronic, including repeated CVC occlusion or sepsis, or prominent venous collaterals on the chest, face, and neck.

**Pulmonary Embolism**

Symptoms of pulmonary embolism (PE) include shortness of breath, pleuritic chest pain, cough, hemoptysis, fever, and, in the case of massive PE, hypotension and right-heart failure. Based on autopsy studies, PE is often not diagnosed, perhaps because young children are unable to accurately describe their symptoms and their respiratory deterioration may be masked by other conditions (see Chapter 407.1).

**Cerebral Sinovenous Thrombosis**

Symptoms may be subtle and may develop over many hours or days. Neonates often present with seizures, whereas older children often complain of headache, vomiting, seizures, and focal signs. They may also have papilledema and abducens palsy. Some patients may have a concurrent sinusitis or mastoiditis that has contributed to the thrombosis.
Renal Vein Thrombosis
Renal vein thrombosis is the most common spontaneous TE in neonates. Affected infants may present with hematuria, an abdominal mass, and/or thrombocytopenia. Infants of diabetic mothers are at increased risk, although the mechanism for this increased risk is unknown. Approximately 25% of cases are bilateral.

Peripheral Arterial Thrombosis
With the exception of stroke, the majority of arterial TEs in children are secondary to catheters, often in neonates related to umbilical artery lines or in patients with cardiac defects undergoing cardiac catheterization. Patients with an arterial thrombosis affecting blood flow to an extremity will present with a cold, pale, extremity with poor or absent pulses.

Stroke
Ischemic stroke commonly presents with hemiparesis, loss of consciousness, or seizures. This condition may occur secondary to pathology that affects the intracranial arteries (e.g., sickle cell disease, vasculopathy, or traumatic arterial dissection) or may be a result of venous thrombi that embolize to the arterial circulation (placental thrombi, children with congenital heart disease or patent foramen ovale).

Rapidly Progressive Thrombosis/Thrombotic Storm
Rapid progression or multifocal thrombosis is a rare complication of the APS, heparin-induced thrombocytopenia with thrombosis or thrombotic thrombocytopenia purpura while on appropriate antithrombotic therapy. Multiple organ dysfunctions develop in the presence of small vessel occlusion and elevated D-dimer levels. Recurrences may occur as well as postthrombotic syndrome (PTS). Treatment includes aggressive anticoagulation, often with direct thrombin inhibitors or fondaparinux followed by prolonged warfarin therapy.

DIAGNOSIS
Ultrasound with Doppler flow is the most commonly employed imaging study for the diagnosis of upper, or more often lower, extremity VTE. Spiral CT is used most frequently for the diagnosis of PE (Fig. 479-1). Other diagnostic imaging options include CT and MR venography, which are noninvasive, although the sensitivity and specificity of these studies is not known. They may be particularly helpful in evaluating proximal thrombosis. For the diagnosis of cerebral sinusovenous thrombosis and acute ischemic stroke, the most sensitive imaging study is brain magnetic resonance imaging with venography or diffusion weighted imaging.

LABORATORY TESTING
All children with a TE should have a complete blood count and a baseline prothrombin time (PT) and activated partial thromboplastin time (aPTT) to assess their coagulation status. In adults suspected to have a DVT, the D-dimer level has a high negative predictive value. The D-dimer is a fragment produced when fibrin is degraded by plasmin and is a measure of fibrinolysis. Based on the clinical scenario, other laboratory studies, such as renal and hepatic function, may be indicated. Testing for APS includes evaluation for the lupus anticoagulant as well as antiphospholipid and anti-β2-glycoprotein antibodies.

There is some debate regarding which patients should have testing for inherited risk factors. Thrombophilia testing rarely influences the acute management of a child with a thrombotic event. Identification of an inherited thrombophilia may influence the duration of treatment, particularly for those with combined defects, and may aid in counseling the patient about their risk of recurrence.

The evaluation of coagulation studies in pediatric patients is often complicated the developing hemostatic system and the differences in normal ranges between infants and adults. In addition, there is often significant variation in the laboratory assays used to test anticoagulant levels. It is important to refer to the age-related normal ranges when interpreting pediatric coagulation studies. One limitation of these normal ranges is that they were performed many years ago, using assays that may not be equivalent to those used today. Molecular assays are not age dependent.

TREATMENT
Therapeutic options for children with thrombosis include anticoagulation, thrombolysis, surgery, and observation. The goal of anticoagulation is to reduce the risk of embolism, halt clot extension, and prevent recurrence. In premature neonates and critically ill children who may have an increased risk of bleeding, the potential benefits must be weighed against the risks. Anticoagulants and thrombolysis are discussed in greater detail in Chapter 479.1. Surgery may be necessary for life- or limb-threatening thrombosis when there is a contraindication to thrombolysis. The optimal treatment for a child with acute ischemic stroke depends on the likely etiology and the size of the infarct. Children with sickle cell disease who develop stroke are treated with chronic red blood cell transfusions to reduce recurrence.

COMPLICATIONS
Complications of VTE include recurrent thrombosis (either local or distant), and development of PTS. A thrombosed blood vessel may partially or fully recanalize or may remain occluded. Over time, an occluded deep vein may cause venous hypertension, resulting in blood flow being directed from the deep system into the superficial veins and potentially producing pain, swelling, edema, discoloration, and ulceration. This clinical picture is known as PTS and may be chronically disabling. Several prospective studies in adults have shown PTS to be present in 17-50% of patients with a history of thrombosis. The likelihood of developing PTS is highest in the first 2 yr but continues to increase over time.

479.1 Anticoagulant and Thrombolytic Therapy
Leslie J. Raffini and J. Paul Scott

Initial options for anticoagulation in children include unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) (Table 479-2). Although there are additional agents, including target specific oral anticoagulants, none have been carefully investigated in children. Both UFH and LMWH act by catalyzing the action of antithrombin (AT)-III. UFH consists of large-molecular-weight polysaccharide chains that interact with AT, catalyzing the inhibition of factor Xa and thrombin, as well as other serine proteases. In contrast, LMWH contains smaller-molecular-weight polysaccharide chains. The interaction of the smaller chains with AT-III results primarily in the inhibition of
Xa, with less of an effect on thrombin. There are several LMWHs available, and they have variable inhibitory effects on thrombin. For this reason, the PTT is not a reliable measure of the anticoagulant effect of LMWH, and the anti–factor Xa activity is used instead.

The optimal duration of anticoagulation for children with TEs is not well established. Current guidelines recommend that neonates receive 6 wk–3 mo of therapy for VTE, and older children receive 3–6 mo of therapy. Patients with strong inherited thrombophilia, recurrent thrombosis, and APS may require indefinite anticoagulation.

**UNFRACTIONATED HEPARIN**

**Heparin Dosing**

Based on adult data, a therapeutic heparin dose achieves a prolongation of the aPTT of 1.5–2.5 the upper limit of normal. A bolus dose of 75–100 units/kg results in a therapeutic PTT in the majority of children. This bolus should be followed by a continuous infusion. Initial dosing is based on age, with infants having the highest requirements. It is important to continue to monitor the PTT closely. In some situations, such as patients with a lupus anticoagulant, elevated factor VIII, or neonates, the partial thromboplastin time may not accurately reflect the degree of anticoagulation, and heparin can be monitored using a heparin anti-Xa level of 0.35–0.7 units/mL.

**Heparin Complications**

Maintaining the aPTT in the therapeutic range can be difficult in young children for several reasons. The bioavailability of heparin is difficult to predict and may be influenced by plasma proteins. In many patients, this results in multiple dose adjustments required by close monitoring with frequent venipuncture. UFH also requires continuous intravenous access, which may be difficult to maintain in young children.

The most common adverse effect related to heparin therapy is bleeding. This is well documented in the adult medical literature, and there are case reports of serious life-threatening bleeding in children treated with heparin. The true frequency of bleeding in pediatric patients on heparin has not been well established and is reported as 1–24%. If the anticoagulant effect of heparin must be reversed immediately, protamine sulfate may be administered to neutralize the heparin.

Other adverse effects include osteoporosis and heparin-induced thrombocytopenia (HIT). Although rare in pediatric populations, HIT is a prothrombotic, immune-mediated complication in which antibodies develop to a complex of heparin and platelet factor 4. These antibodies result in platelet activation, stimulation of coagulation, thrombocytopenia, and in some cases, life-threatening thrombosis. If HIT is strongly suspected, heparin must be discontinued immediately. There are several alternative parenteral anticoagulants (argatroban, lepirudin, or bivalirudin) that may be used in this situation.

**LOW-MOLECULAR-WEIGHT HEPARIN**

Because of the ease of dosing and need for less monitoring, LMWH is being used more frequently in pediatric patients. Unlike UFH, which is monitored using the aPTT, LMWH is monitored via the anti-Xa activity. The LMWH formulation that has been used most often in pediatric patients is enoxaparin.

**Enoxaparin Dosing**

The recommended standard starting dose of enoxaparin for infants <2 mo is 1.5 mg/kg/dose SQ every 12 hr; for patients >2 mo it is 1 mg/kg SQ every 12 hr. In general, peak levels are achieved 2–6 hr following an injection. A therapeutic anti–factor Xa level, drawn 4 hr after the 2nd or 3rd dose, should be between 0.5 and 1.0 IU/mL. The dose can be titrated to achieve this range. The elimination half-life of enoxaparin is 4–6 hr. Enoxaparin is cleared by the kidney and should be used with caution in patients with renal insufficiency. It should be avoided in patients with renal failure.

After an initial period of anticoagulation with heparin or LMWH, patients may continue to receive LMWH as an outpatient for the duration of therapy, or may be transitioned to an oral anticoagulant, such as warfarin.

**WARFARIN**

Warfarin is an oral anticoagulant that competitively interferes with vitamin K metabolism, exerting its action by decreasing concentrations of the vitamin K–dependent coagulation factors II, VII, IX, and X, as well as protein C and protein S. Therapy should be started while a patient is anticoagulated with heparin or LMWH because of the risk of warfarin-induced skin necrosis. This transient hypercoagulable condition may occur when levels of protein C drop more rapidly than the procoagulant factors.

**Warfarin Dosing**

Warfarin therapy is often initiated with a loading dose, with subsequent dose adjustments made according to a nomogram. When initiating a patient on warfarin, UFH or LMWH should be continued until the international normalized ratio (INR) is therapeutic for 2 days. In most cases, this takes 5–7 days. The PT is used to monitor the anticoagulant effect of warfarin. Because the thromboplastin reagents used in PT assays have widely varying sensitivities, it is not possible to compare the PT performed in one laboratory to that performed in another laboratory. As a result, the INR was developed as a mechanism to standardize the variation in the thromboplastin reagent. The target INR range depends on the clinical situation. In general, a range of 2.0–3.0 is the target for the treatment of VTE. High-risk patients, such as those with mechanical heart valves, APS, and recurrent thrombosis, may require a higher target range.

FDP, fibrin degradation product; INR, international normalized ratio; LMW, low-molecular-weight; PTT, partial thromboplastin time; rTPA, recombinant tissue-type plasminogen activator.

*Higher dose is required in newborns.*
**THROMBOLYTIC THERAPY**

Although anticoagulation alone is often effective at managing thrombosis, there are times when more rapid clot resolution is necessary or desirable. In these situations, thrombolytic agents that activate the fibrinolytic system are of potential benefit. The pharmacologic activity of thrombolytic agents is dependent on the conversion of endogenous plasminogen to plasmin. Plasmin is then able to degrade several plasma proteins including fibrin and fibrinogen. Because of the high risk of bleeding, thrombolytic therapy is generally reserved for patients with life or limb-threatening thrombosis.

**Tissue plasminogen activator** (TPA) is available as a recombinant product and has become the primary agent used for thrombolysis in children, although proper dose finding studies have not been performed in a pediatric population.

**Dosing**

There is an extremely wide range of doses of TPA that have been used for systemic therapy, and there is no consensus as to the optimal dose. Previously recommended doses of systemic TPA were 0.1–0.6 mg/kg/hr; however there are recent reports of successful therapy with fewer bleeding complications using prolonged infusions with very low doses—0.01-0.06 mg/kg/hr.

**Monitoring**

There is no specific laboratory test to document a “therapeutic range” for thrombolytic therapy. It is important to maintain the fibrinogen >100 mg/dL and the platelet count >75,000/mm³ during treatment. Supplementation of plasminogen using fresh-frozen plasma is generally recommended in neonates prior to initiating thrombolysis because of their low baseline levels.

The clinical and radiologic response to thrombolysis should be closely monitored. The duration of therapy depends on the clinical response. Invasive procedures including urinary catheterization, arterial puncture and rectal temperatures should be avoided.

The role of adjuvant UFH during thrombolytic therapy is controversial. Animal models have demonstrated that thrombolytic therapy can induce a procoagulant state with activation of the coagulation system, generation of thrombin, and extension or reocclusion of the thrombus. In pediatric patients thought to be at low risk for bleeding, adjuvant UFH should be considered using doses of 10-20 units/kg/hr.

**Complications**

The most serious complication from thrombolysis is bleeding, which has been reported in 0-40% of patients. Absolute contraindications to thrombolysis include major surgery within 7 days, history of significant bleeding (intracranial, pulmonary or gastrointestinal), peripartum asphyxia with brain damage, uncontrolled hypertension and severe thrombocytopenia. In the event of serious bleeding, thrombolysis should be stopped and cryoprecipitate may be given to replace fibrinogen.

**THROMBOPROPHYLAXIS**

There have been no formal trials of prevention of venous thromboembolic disease in children. Hospitalized adolescents with multiple risk factors for thrombosis who are immobilized for a protracted time may benefit from prophylactic treatment with enoxaparin 0.5 mg/kg q12hr (maximum: 30 mg).

**ANTIPLATELET THERAPY**

Inhibition of platelet function using agents such as aspirin is more likely to be protective against arterial TEs than VTEs. Aspirin, also known as acetylsalicylic acid, exerts its antiplatelet effect by irreversibly inhibiting cyclooxygenase, preventing platelet thromboxane A₂ production. Aspirin is used routinely in children with Kawasaki disease and may also be useful in children with stroke, ventricular assist devices, and those with single-ventricle cardiac defects. The recommended dose of aspirin to achieve an antiplatelet effect in children is 1-5 mg/kg/day.

*Bibliography is available at Expert Consult.*
Bibliography

Although "late" hemorrhagic disease has been reported in breastfed children, vitamin K deficiency occurring after the neonatal period is usually secondary to a lack of oral intake of vitamin K, alterations in the gut flora as a consequence of the long-term use of broad-spectrum antibiotics, liver disease, or malabsorption of vitamin K. Intestinal malabsorption of fats may accompany cystic fibrosis or biliary atresia and result in a deficiency of fat-soluble dietary vitamins, with reduced synthesis of vitamin K–dependent clotting factors (factors II, VII, IX, and X, and proteins C and S). Prophylactic administration of water-soluble vitamin K orally is indicated in these cases (2-3 mg/24 hr for children and 5-10 mg/24 hr for adolescents and adults), or vitamin K may be administered at 1-2 mg IV. In patients with advanced cirrhosis, synthesis of many of the clotting factors may be reduced because of hepatocellular damage. In these patients, vitamin K may be ineffective. The anticoagulant properties of warfarin (Coumadin) and related anticoagulants depend on interference with vitamin K, with a concomitant reduction of factors II, VII, IX, and X. Rat poison (superwarfarin) produces a similar deficiency; vitamin K is a specific antidote.

Bibliography is available at Expert Consult.
Bibliography
Because all of the clotting factors, except factor VIII, are produced exclusively in the liver, coagulation abnormalities are very common in patients with severe liver disease. Only 15% of such patients have significant clinical bleeding states. The severity of the coagulation abnormality appears to be directly proportional to the extent of hepatocellular damage. The most common mechanism causing the defect is decreased synthesis of coagulation factors. Patients with severe liver disease characteristically have normal to increased (not reduced) levels of factor VIII activity in plasma. In some instances, disseminated intravascular coagulation (see Chapter 483) or hyperfibrinolysis may complicate liver disease, making laboratory differentiation of severe liver disease from disseminated intravascular coagulation difficult.

Treatment of the coagulopathy of liver disease should be reserved for patients with clinical bleeding. Because a reduction in vitamin K–dependent coagulation factors is common in those with acute or chronic liver disease, vitamin K therapy can be given as a trial. Vitamin K can be given orally, subcutaneously, or intravenously (not intramuscularly) at a dose of 1 mg/24 hr for infants, 2-3 mg/24 hr for children, and 5-10 mg/24 hr for adolescents and adults. Inability to correct coagulopathy with vitamin K indicates that the coagulopathy may be caused by reduced levels of clotting factors that are not vitamin K–dependent and/or by inadequate production of precursor vitamin K proteins. Treatment for bleeding consists of factor replacement with fresh-frozen plasma (FFP) or cryoprecipitate. FFP (10-15 mL/kg) contains all clotting factors, but replacement of fibrinogen for severe hypofibrinogenemia may require cryoprecipitate at a dose of 1 bag/5 kg body weight. In severe liver disease, it is often difficult to attain correction of abnormal clotting studies despite vigorous therapy with FFP and cryoprecipitate. Some patients with bleeding as a result of liver disease have responded to therapy with desmopressin, and others have responded to treatment with recombinant factor VIIa.

Frequently, severe liver disease is associated with moderate prolongation of bleeding time that is not corrected by either vitamin K or plasma replacement. Desmopressin (0.3 µg/kg IV) is effective in shortening bleeding time and is used effectively to augment hemostasis before liver biopsy. In clinical trials of adults, recombinant factor VIIa has not been shown to be effective for the treatment of bleeding caused by severe liver disease.

Bibliography
Acquired circulating anticoagulants (inhibitors) are antibodies that react or crossreact with clotting factors or components used in coagulation screening tests (phospholipids), thereby prolonging screening tests, such as prothrombin time and partial thromboplastin time. Some of these anticoagulants are autoantibodies that react with phospholipid and thereby interfere with clotting in vitro but not in vivo. The most common form of these antiphospholipid antibodies has been referred to as the lupus anticoagulant (see Chapter 476.1). This anticoagulant is found in patients with systemic lupus erythematosus (see Chapter 158), in those with other collagen-vascular diseases, and in association with HIV. In otherwise healthy children, spontaneous lupus-like inhibitors have developed transiently after incidental viral infection. These transient inhibitors are usually not associated with either bleeding or thrombosis.

Although the classic lupus anticoagulant is more often associated with a predisposition to thrombosis than with bleeding symptoms, bleeding symptoms in a patient with the lupus anticoagulant may be caused by thrombocytopenia, as a manifestation of the antiphospholipid syndrome or of lupus itself, or, rarely, by a coexistent specific autoantibody against prothrombin (factor II). This antiprothrombin antibody does not inactivate prothrombin, but causes accelerated clearance of the protein, resulting in low levels of prothrombin.

Rarely, antibodies may arise spontaneously against a specific clotting factor, such as factor VIII or von Willebrand factor, similar to those seen more frequently in elderly patients. These patients are prone to excessive hemorrhage and may require specific treatment. In patients with a hereditary deficiency of a clotting factor (factor VIII or factor IX), antibodies may develop after exposure to transfused factor concentrates. These hemophilic inhibitory antibodies are discussed in Chapter 479.1.

LABORATORY FINDINGS
Inhibitors against specific coagulation factors usually affect factors VIII, IX, and XI, or, rarely, prothrombin. Depending on the target of the antibody, prothrombin time, partial thromboplastin time, or both may be prolonged. The mechanism by which the inhibitory antibody functions determines whether mixing patient plasma with normal plasma will normalize (correct) the clotting time. Patient plasma containing antibodies directed against the active site of the clotting factor (factor VIII or factor IX) will not correct on 1:1 mixing with normal plasma, whereas antibodies that lead to increased clearance of the factor (prothrombin) will correct on 1:1 mixing. Specific factor assays are used to determine which factor is involved.

TREATMENT
Management of the bleeding patient with an inhibitor against factor VIII or IX is the same as for the patient with hemophilia who has an alloantibody against factor VIII or factor IX. Infusions of recombinant factor VIIa or activated prothrombin complex concentrate may be needed to control significant bleeding. Immunosuppressive agents have used off-label to treat the inhibitor or reduce titers. Acute bleeding caused by an antiprothrombin antibody can often be treated with a plasma infusion and may benefit from a short course of corticosteroid therapy.

Asymptomatic spontaneous inhibitors that arise after a viral infection tend to disappear within a few weeks to months. Inhibitors seen with an underlying disease, such as systemic lupus erythematosus, often disappear when the primary disease is effectively treated.

Bibliography

Thrombotic microangiopathy refers to a heterogeneous group of conditions, including disseminated intravascular coagulation (DIC), that result in consumption of clotting factors, platelets, and anticoagulant proteins. Consequences of this process include widespread intravascular deposition of fibrin, leading to tissue ischemia and necrosis, a generalized hemorrhagic state, and hemolytic anemia.

ETIOLOGY

Any life-threatening severe systemic disease (Table 483-1) associated with hypoxia, acidosis, tissue necrosis, shock, and/or endothelial damage may trigger DIC. Better understanding of the pathophysiology of hemostasis has led to an appreciation of the critical interaction of the coagulation pathways with the innate immune system and inflammatory response that likely contributes to the widespread dysregulation present in DIC. Activation and release of cytokines and chemokines alter endothelial function to a more prothrombotic state, enhancing the formation of microvascular thromboses, with resultant consumption of pro- and anticoagulant proteins. Excessive activation of clotting consumes both the physiologic anticoagulants (protein C, protein S, and antithrombin III) and procoagulants, resulting in a deficiency of factor V, factor VIII, prothrombin, fibrinogen, and platelets. Commonly, the clinical result of this sequence of events is hemorrhage. The hemostatic dysregulation may also result in thromboses in the skin, kidneys, and other organs.

CLINICAL MANIFESTATIONS

DIC accompanies a severe systemic disease process, usually with shock. Bleeding frequently first occurs from sites of venipuncture or surgical incision. The skin may show petechiae and ecchymoses. Tissue necrosis may involve many organs and can be most spectacularly seen as infarction of large areas of skin, subcutaneous tissue, or kidneys. Anemia caused by hemolysis may develop rapidly, owing to microangiopathic hemolytic anemia.

LABORATORY FINDINGS

There is no well-defined sequence of events. Certain coagulation factors (factors II, V, and VIII, and fibrinogen) and platelets may be consumed by the ongoing intravascular clotting process, with resultant prolongation of the prothrombin, partial thromboplastin, and thrombin times. Platelet counts may be profoundly depressed. The blood smear may contain fragmented, burl- and helmet-shaped red blood cells (schistocytes). In addition, because the fibrinolytic mechanism is activated, fibrinogen degradation products (D-dimers) appear in the blood. The D-dimer is formed by fibrinolysis of a crosslinked fibrin clot. The D-dimer assay is as sensitive as the fibrinogen degradation assay for detection of disseminated intravascular coagulation.

TREATMENT

The first 2 steps in the treatment of DIC are the most critical: (a) treat the trigger that caused DIC and (b) restore normal homeostasis by correcting the shock, acidosis, and hypoxia that usually complicate DIC. If the underlying problem can be controlled and the patient stabilized, bleeding quickly ceases, and there is improvement of the abnormal laboratory findings. Blood components are used for replacement therapy in patients with hemorrhage and may consist of platelet infusions (for thrombocytopenia), cryoprecipitate (for hypofibrinogenemia), and/or fresh-frozen plasma (for replacement of other coagulation factors and natural inhibitors).

The role of heparin in DIC is limited to patients who have vascular thrombosis in association with DIC or who require prophylaxis because they are at high risk for venous thromboembolism. Such individuals should be treated as outlined in Chapter 479, with careful attention to replacement therapy to maintain an adequate platelet count and thus limit bleeding complications.

MEGAKARYOPOIESIS

Platelets are nonnucleated cellular fragments produced by megakaryocytes within the bone marrow and other tissues. Megakaryocytes are large polyploid cells. When the megakaryocyte approaches maturity, budding of the cytoplasm occurs and large numbers of platelets are liberated. Platelets circulate with a life span of 10-14 days.

Thrombopoietin (TPO) is the primary growth factor that controls platelet production (Fig. 484-1). Levels of TPO appear to correlate inversely with platelet number and megakaryocyte mass. Levels of TPO are highest in the thrombocytopenic states associated with decreased marrow megakaryopoiesis and may be variable in states of increased platelet production.

The platelet plays multiple hemostatic roles. The platelet surface possesses a number of important receptors for adhesive proteins, including von Willebrand factor (VWF) and fibrinogen, as well as receptors for agonists that trigger platelet aggregation, such as thrombin, collagen, and adenosine diphosphate (ADP). After injury to the blood vessel wall, the extracellular matrix containing adhesive and procoagulant proteins is exposed. Subendothelial collagen binds VWF. VWF undergoes a conformational change that induces binding of the platelet glycoprotein Ib (GPIb) complex, the VWF receptor. This process is called platelet adhesion. Platelets then undergo activation. During the process of activation, the platelets generate thromboxane A2 from arachidonic acid via the enzyme cyclooxygenase. After activation, platelets release agonists, such as ADP, adenosine triphosphate (ATP), Ca2+, serotonin, and coagulation factors, into the surrounding milieu. Binding of VWF to the GPIb complex triggers a complex signaling cascade that results in activation of the fibrinogen receptor, the major platelet integrin glycoprotein αIIb-β3 (GPIIb-IIIa). Circulating fibrinogen binds to its receptor on the activated platelets, complex linking platelets together in a process called aggregation. This series of events forms a hemostatic plug at the site of vascular injury. The serotonin and histamine that are liberated during activation increase local vasoconstriction. In addition to acting in concert with the vessel wall to form the platelet plug, the platelet provides the catalytic surface on which coagulation factors assemble and eventually generate thrombin through a sequential series of enzymatic cleavages. Last, the platelet contractile proteins and cytoskeleton mediate clot retraction.

THROMBOCYTOPENIA

The normal platelet count is 150-450 × 10^9/L. Thrombocytopenia refers to a reduction in platelet count to <150 × 10^9/L. Causes of thrombocytopenia include decreased production on either a congenital or an acquired basis, sequestration of the platelets within an enlarged spleen or other organ, and increased destruction of normally synthesized platelets on either an immune or a nonimmune basis (see Chapter 475; Tables 484-1 and 484-2 and Fig. 484-2).

*The most common conditions are shown in bold.

CAMT, congenital amegakaryocytic thrombocytopenia; CMV, cytomegalovirus; DIC, disseminated intravascular coagulation; GBS, group B streptococcus; ITP, idiopathic thrombocytopenic purpura; IUGR, intrauterine growth restriction; NEC, necrotizing enterocolitis; PET, preeclampsia; SLE, systemic lupus erythematosus; TAR, thrombocytopenia with absent radii.

The most common cause of acute onset of thrombocytopenia in an otherwise well child is (autoimmune) idiopathic thrombocytopenic purpura (ITP).

**EPIDEMIOLOGY**
In a small number of children, estimated at 1 in 20,000, 1-4 wk after exposure to a common viral infection, an autoantibody directed against the platelet surface develops with resultant sudden onset of thrombocytopenia. A recent history of viral illness is described in 50-65% of cases of childhood ITP. The peak age is 1-4 yr, although the age ranges from early in infancy to the elderly. In childhood, males and females are equally affected. ITP seems to occur more often in late winter and spring after the peak season of viral respiratory illness.

**PATHOGENESIS**
Why some children develop the acute presentation of an autoimmune disease is unknown. The exact antigenic target for most such antibodies in most cases of childhood acute ITP remains undetermined. Although in chronic ITP, many patients demonstrate antibodies against the platelet glycoprotein complexes, αIIb-β3, and GPIb. After binding of the antibody to the platelet surface, circulating antibody-coated platelets are recognized by the Fc receptor on splenic macrophages, ingested, and destroyed. Most common viruses have been described in association with ITP, including Epstein-Barr virus (see Chapter 254) and HIV (see Chapter 276). Epstein-Barr virus-related ITP is usually of short duration and follows the course of infectious mononucleosis. HIV-associated ITP is usually chronic. In some patients ITP appears to arise in children infected with *Helicobacter pylori* or rarely following vaccines.

**CLINICAL MANIFESTATIONS**
The classic presentation of ITP is a previously healthy 1-4 yr old child who has sudden onset of generalized petechiae and purpura. The parents often state that the child was fine yesterday and now is covered with bruises and purple dots. There may be bleeding from the gums and mucous membranes, particularly with profound thrombocytopenia (platelet count <10 x 10^9/L). There is a history of a preceding viral infection 1-4 wk before the onset of thrombocytopenia. Findings on physical examination are normal, other than the finding of petechiae and purpura. Splenomegaly, lymphadenopathy, bone pain, and pallor are rare. An easy to use classification system has been proposed from the United Kingdom to characterize the severity of bleeding in ITP on the basis of symptoms and signs, but not platelet count:
1. No symptoms
2. Mild symptoms: bruising and petechiae, occasional minor epistaxis, very little interference with daily living
3. Moderate: more severe skin and mucosal lesions, more troublesome epistaxis and menorrhagia
4. Severe: bleeding episodes—menorrhagia, epistaxis, melena—requiring transfusion or hospitalization, symptoms interfering seriously with the quality of life

The presence of abnormal findings such as hepatosplenomegaly, bone or joint pain, remarkable lymphadenopathy other cytopenias, or congenital anomalies suggests other diagnoses (leukemia, syndromes). When the onset is insidious, especially in an adolescent, chronic ITP or the possibility of a systemic illness, such as systemic lupus erythematosus (SLE), is more likely.

**OUTCOME**
Severe bleeding is rare (<3% of cases in 1 large international study). In 70-80% of children who present with acute ITP, spontaneous resolution occurs within 6 mo. Therapy does not appear to affect the natural history of the illness. Fewer than 1% of patients develop an intracranial hemorrhage. Those who favor interventional therapy argue that the objective of early therapy is to raise the platelet count to >20 x 10^9/L and prevent the rare development of intracranial hemorrhage. There is no evidence that therapy prevents serious bleeding. Approximately 20% of children who present with acute ITP go on to have chronic ITP. The outcome/prognosis may be related more to age, as ITP in younger children is more likely to resolve whereas the development of chronic ITP in adolescents approaches 50%.

**LABORATORY FINDINGS**
Severe thrombocytopenia (platelet count <20 x 10^9/L) is common, and platelet size is normal or increased, reflective of increased platelet turnover (Fig. 484-3). In acute ITP, the hemoglobin value, white blood cell (WBC) count, and differential count should be normal. Hemoglobin may be decreased if there have been profuse nosebleeds or menorrhagia. Bone marrow examination shows normal granulocytic and erythrocytic series, with characteristically normal or increased
numbers of megakaryocytes. Some of the megakaryocytes may appear to be immature and are reflective of increased platelet turnover. **Indications for bone marrow** aspiration/biopsy include an abnormal WBC count or differential or unexplained anemia as well as findings on history and physical examination suggestive of a bone marrow failure syndrome or malignancy. Other laboratory tests should be performed as indicated by the history and physical examination. HIV studies should be done in at-risk populations, especially sexually active teens. Platelet antibody testing is seldom useful in acute ITP. A direct antiglobulin test (Coombs) should be done if there is unexplained anemia to rule out Evans syndrome (autoimmune hemolytic anemia and thrombocytopenia) (see Chapter 458) or before instituting therapy with IV anti-D.

**DIAGNOSIS/DIFFERENTIAL DIAGNOSIS**

The well-appearing child with moderate to severe thrombocytopenia, an otherwise normal complete blood cell count (CBC), and normal findings on physical examination has a limited differential diagnosis that includes exposure to medication that induces drug-dependent antibodies, splenic sequestration because of previously unappreciated portal hypertension, and, rarely, early aplastic processes, such as Fanconi anemia (see Chapter 468). Other than congenital thrombocytopenia syndromes (see Chapter 484.8), such as thrombocytopenia-absent radius (TAR) syndrome and MYH9-related thrombocytopenia, most marrow processes that interfere with platelet production eventually cause abnormal synthesis of red blood cells (RBCs) and WBCs, and therefore manifest diverse abnormalities on the CBC. Disorders that cause increased platelet destruction on a nonimmune basis are usually serious systemic illnesses with obvious clinical findings (e.g., hemolytic-uremic syndrome [HUS], disseminated intravascular coagulation [DIC]) (see Table 483-1 in Chapter 483, and Fig. 484-2). Patients on heparin may develop heparin-induced thrombocytopenia. Isolated enlargement of the spleen suggests the potential for hypersplenism owing to either liver disease or portal vein thrombosis. Autoimmune thrombocytopenia may be an initial manifestation of SLE, HIV infection, common variable immunodeficiency, and, rarely, lymphoma or autoimmune lymphoproliferative syndrome. Wiskott-Aldrich syndrome (WAS; Chapter 126.2) must be considered in young males found to have thrombocytopenia with small platelets, particularly if there is a history of eczema and recurrent infection.

**TREATMENT**

There are no data showing that treatment affects either short- or long-term clinical outcome of ITP. Many patients with new-onset ITP have mild symptoms, with findings limited to petechiae and purpura on the skin, despite severe thrombocytopenia. Compared with untreated control subjects, treatment appears to be capable of inducing a more rapid rise in platelet count to the theoretically safe level of >20 × 10⁹/L, although there are no data indicating that early therapy prevents intracranial hemorrhage. Antiplatelet antibodies bind to transfused platelets as well as they do to autologous platelets. Thus, platelet transfusion in ITP is usually contraindicated unless life-threatening bleeding is present. Initial approaches to the management of ITP include the following:

1. No therapy other than education and counseling of the family and patient for patients with minimal, mild, and moderate symptoms, as defined earlier. This approach emphasizes the usually benign nature of ITP and avoids the therapeutic roller coaster that ensues once interventional therapy is begun. This approach is far less costly, and side effects are minimal.

2. Per the American Society of Hematology Guidelines: “A single dose of IVIG [intravenous immunoglobulin] (0.8-1.0 g/kg) or a short course of corticosteroids should be used as first-line treatment." IVIG at a dose of 0.8-1.0 g/kg/day for 1-2 days induces a rapid rise in platelet count (usually >20 × 10⁹/L) in 95% of patients within 48 hr. IVIG appears to induce a response by downregulating Fc-mediated phagocytosis of antibody-coated platelets. IVIG therapy is both expensive and time-consuming to administer. Additionally, after infusion, there is a high frequency of headaches and vomiting, suggestive of IVIG-induced aseptic meningitis.

3. Prednisone. Corticosteroid therapy has been used for many years to treat acute and chronic ITP in adults and children. Doses of prednisone of 1-4 mg/kg/24 hr appear to induce a more rapid rise in platelet count than in untreated patients with ITP.

Corticosteroid therapy is usually continued for short course until a rise in platelet count to >20 × 10⁹/L has been achieved to avoid the long-term side effects of corticosteroid therapy, especially growth failure, diabetes mellitus, and osteoporosis.

4. Intravenous anti-D therapy. For Rh-positive patients, IV anti-D at a dose of 50-75 µg/kg causes a rise in platelet count to >20 × 10⁹/L in 80-90% of patients within 48-72 hr. When given to Rh-positive individuals, IV anti-D induces mild hemolytic anemia. RBC-antibody complexes bind to macrophage Fc receptors and interfere with platelet destruction, thereby causing a rise in platelet count. IV anti-D is ineffective in Rh-negative patients. Rare life-threatening episodes of intravascular hemolysis have occurred in children and adults following infusion of IV anti-D. Each of these medications may be used to treat ITP exacerbations, which commonly occur several weeks after an initial course of therapy. In the special case of intracranial hemorrhage, multiple modalities should be used, including platelet transfusion, IVIG, high-dose corticosteroids, and prompt consultation by neurosurgery and surgery.

There is no consensus regarding the management of acute childhood ITP, except that patients who are bleeding significantly (less than 5% of children with ITP) should be treated. Intracranial hemorrhage
remains rare, and there are no data showing that treatment actually reduces its incidence.

The role of splenectomy in ITP should be reserved for 1 of 2 circumstances. The older child (≥4 yr) with severe ITP that has lasted >1 yr (chronic ITP) and whose symptoms are not easily controlled with therapy is a candidate for splenectomy. Splenectomy must also be considered when life-threatening hemorrhage (intracranial hemorrhage) complicates acute ITP; if the platelet count cannot be corrected rapidly with transfusion of platelets and administration of IVIG and corticosteroids. Splenectomy is associated with a lifelong risk of overwhelming postsplenectomy infection caused by encapsulated organisms, increased risk of thrombosis, and the potential development of pulmonary hypertension in adulthood. As an alternative to splenectomy, rituximab has been used off-label in children to treat chronic ITP. In 30-40% of children, rituximab has induced a partial or complete remission.

**CHRONIC AUTOIMMUNE THROMBOCYTOPENIC PURPURA**

Approximately 20% of patients who present with acute ITP have persistent thrombocytopenia for >12 mo and are said to have chronic ITP. At that time, a careful reevaluation for associated disorders should be performed, especially for autoimmune disease, such as SLE; chronic infectious disorders, such as HIV; and nonimmune causes of chronic thrombocytopenia, such as type 2B and platelet-type von Willebrand disease, X-linked thrombocytopenia, autoimmune lymphoproliferative syndrome, common variable immunodeficiency syndrome, autosomal macrothrombocytopenia, and WAS (also X-linked). The presence of coexisting _H. pylori_ infection should be considered and, if found, treated. Therapy should be aimed at controlling symptoms and preventing serious bleeding. In ITP, the spleen is the primary site of both antiplatelet antibody synthesis and platelet destruction. Splenectomy is successful in inducing complete remission in 64-88% of children with chronic ITP. This effect must be balanced against the lifelong risk of overwhelming postsplenectomy infection. This decision is often affected by quality of life issues, as well as the ease with which the child can be managed using medical therapy, such as IVIG, corticosteroids, IV anti-D, or rituximab. Two effective agents that act to stimulate thrombopoiesis, romiplostim and eltrombopag (see Fig. 484-1), are approved by the FDA to treat adults with chronic ITP. Preliminary data using thrombopoietic agents in children are encouraging.

**484.2 Drug-Induced Thrombocytopenia**

_J. Paul Scott_

A number of drugs are associated with immune thrombocytopenia as the result of either an immune process or megakaryocyte injury. Some common drugs used in pediatrics that cause thrombocytopenia include valproic acid, phenytoin, carbamazepine, sulfonamides, vancomycin, and trimethoprim-sulfamethoxazole. Heparin-induced thrombocytopenia (and, rarely, an associated thrombosis) is seldom seen in pediatrics, but it occurs when, after exposure to heparin, the patient has an antibody directed against the heparin–platelet factor 4 complex. Recommended treatment for heparin-induced thrombocytopenia in adults includes argatroban, lepirudin, or danaparoid.

_Bibliography is available at Expert Consult._

**484.3 Nonimmune Platelet Destruction**

_J. Paul Scott_

The syndromes of DIC (see Chapter 483), HUS (see Chapters 484.4 and 518), and thrombotic thrombocytopenic purpura (TTP) (see Chapter 484.5) share the hematologic picture of a thrombotic microangiopathy in which there is RBC destruction and consumptive thrombocytopenia caused by platelet and fibrin deposition in the microvasculature. The microangiopathic hemolytic anemia is characterized by the presence of RBC fragments, including helmet cells, schistocytes, spherocytes, and burr cells.

**484.4 Hemolytic-Uremic Syndrome**

See Chapter 518.

**484.5 Thrombotic Thrombocytopenic Purpura**

_J. Paul Scott_

TTP is a rare pentad of fever, microangiopathic hemolytic anemia, thrombocytopenia, abnormal renal function, and central nervous system changes that is clinically similar to HUS, although TTP can be congenital, it usually presents in adults and occasionally in adolescents. Microvascular thrombi within the central nervous system cause subtle, shifting neurologic signs that vary from changes in affect and orientation to aphasia, blindness, and seizures. Initial manifestations are often nonspecific (weakness, pain, emesis); prompt recognition of this disorder is critical. Laboratory findings provide important clues to the diagnosis and show microangiopathic hemolytic anemia characterized by morphologically abnormal RBCs, with schistocytes, spherocytes, helmet cells, and an elevated reticulocyte count in association with thrombocytopenia. Coagulation studies are usually nondiagnostic. Blood urea nitrogen and creatinine are sometimes elevated. The treatment of TTP is plasmapheresis (plasma exchange), which is effective in 80-95% of cases. Treatment with plasmapheresis should be instituted on the basis of thrombocytopenia and microangiopathic hemolytic anemia even if other symptoms are not yet present. Rituximab, corticosteroids, and splenectomy are reserved for refractory cases.

The majority of cases of TTP are caused by an autoantibody-mediated deficiency of a metalloproteinase (ADAMTS-13) that is responsible for cleaving the high-molecular-weight multimers of VWF and appears to play a pivotal role in the evolution of the thrombotic microangiopathy. In contrast, levels of the metalloproteinase in HUS are usually normal. Congenital deficiency of the metalloproteinase causes rare familial cases of TTP/HUS, usually manifested as recurrent episodes of thrombocytopenia, hemolytic anemia, and renal involvement, with or without neurologic changes, that often present in infancy after an intercurrent illness. Abnormalities of the complement system have now also been implicated in rare cases of familial TTP. ADAMTS-13 deficiency can be treated by repeated infusions of fresh-frozen plasma.

**484.6 Kasabach-Merritt Syndrome**

_J. Paul Scott_

See also Chapter 650.

The association of a giant hemangioma with localized intravascular coagulation causing thrombocytopenia and hypofibrinogenemia is called _Kasabach-Merritt syndrome_. In most patients, the site of the hemangioma is obvious, but retroperitoneal and intraabdominal hemangiomas may require body imaging for detection. Inside the hemangioma there is platelet trapping and activation of coagulation, with fibrinogen consumption and generation of fibrinogen degradation products. Arteriosclerotic malformation within the lesions can cause heart failure. Pathologically, Kasabach-Merritt syndrome appears to develop more often as a result of a kaposiform hemangioendothelioma...
Bibliography
Bibliography

Bibliography
or tufted hemangioma rather than a simple hemangioma. The peripheral blood smear shows microangiopathic changes. Multiple modalities have been used to treat Kasabach-Merritt syndrome, including propranolol, surgical excision (if possible), laser photocoagulation, high-dose corticosteroids, local radiation therapy, antiangiogenic agents, such as interferon-\(\alpha\), and vincristine. Over time, most patients who present in infancy have regression of the hemangioma. Treatment of the associated coagulopathy may benefit from a trial of antifibrinolytic therapy with \(\epsilon\)-aminocaproic acid (Amicar).

### 484.7 Sequestration

**J. Paul Scott**

Thrombocytopenia develops in individuals with massive splenomegaly because the spleen acts as a sponge for platelets and sequesters large numbers. Most such patients also have mild leukopenia and anemia on CBC. Individuals who have thrombocytopenia caused by splenic sequestration should undergo a work-up to diagnose the etiology of splenomegaly, including infectious, inflammatory, infiltrative, neoplastic, obstructive, and hemolytic causes.

### 484.8 Congenital Thrombocytopenic Syndromes

**J. Paul Scott**

See Table 484-2.

Congenital amegakaryocytic thrombocytopenia (CAMT) usually manifests within the 1st few days to week of life, when the child presents with petechiae and purpura caused by profound thrombocytopenia. CAMT is caused by a rare defect in hematopoiesis as a result of a mutation in the stem cell TPO receptor (MPL). Other than skin and mucous membrane abnormalities, findings on physical examination are normal. Examination of the bone marrow shows an absence of megakaryocytes. These patients often progress to marrow failure (aplasia) over time. Hematopoietic stem cell transplantation is curative.

TAR syndrome consists of thrombocytopenia (absence or hypoplasia of megakaryocytes) that presents in early infancy with bilateral radial anomalies of variable severity, ranging from mild changes to marked limb shortening (Fig. 484-4). Many such individuals also have other skeletal abnormalities of the ulna, radius, and lower extremities. Thumbs are present. Intolerance to cow’s milk formula (present in 50%) may complicate management by triggering gastrointestinal bleeding, increased thrombocytopenia, eosinophilia, and a leukemoid reaction. The thrombocytopenia of TAR syndrome frequently remits over the 1st few yrs of life. The molecular basis of TAR syndrome remains to be defined. A few patients have been reported to have a syndrome of amegakaryocytic thrombocytopenia with radioulnar synostosis caused by a mutation in the \(HOXA11\) gene. Different from TAR syndrome, this mutation causes marrow aplasia.

WAS is characterized by thrombocytopenia, with tiny platelets, eczema, and recurrent infection as a consequence of immune deficiency (see Chapter 126.2). WAS is inherited as an X-linked disorder, and the gene for WAS has been sequenced. The WAS protein appears to play an integral role in regulating the cytoskeletal architecture of both platelets and T lymphocytes in response to receptor-mediated cell signaling. The WAS protein is common to all cells of hematopoietic lineage. Molecular analysis of families with X-linked thrombocytopenia has shown that many affected members have a point mutation within the WAS gene, whereas individuals with the full manifestation of WAS have large gene deletions. Examination of the bone marrow in WAS shows the normal number of megakaryocytes, although they may have bizarre morphologic features. Transfused platelets have a normal life span. Splenectomy often corrects the thrombocytopenia, suggesting that the platelets formed in WAS have accelerated destruction. After splenectomy, these patients are at increased risk for overwhelm-

![Figure 484-4](image-url)
May–Hegglin, and Fechtner syndromes, are characterized by autosomal dominant macrothrombocytopenia, neutrophil inclusion bodies, and a variety of physical anomalies, including sensorineural deafness, renal disease, and/or eye disease. These have all been shown to be caused by different mutations in the \( MYH9 \) gene (nonmuscle myosin-IIa heavy chain). The thrombocytopenia is usually mild and not progressive. Some other individuals with recessively inherited macrothrombocytopenia have abnormalities in chromosome 22q11. Mutations in the gene for glycoprotein Ib/β, an essential component of the platelet VWF receptor, can result in Bernard-Soulier syndrome (see Chapter 484.13).

**Bibliography is available at Expert Consult.**

### 484.9 Neonatal Thrombocytopenia

**J. Paul Scott**

See also Chapter 103.4. Thrombocytopenia in the newborn rarely is indicative of a primary disorder of megakaryopoiesis but more often is the result of either systemic illness or transfer of maternal antibodies directed against fetal platelets (see Table 484–2). Neonatal thrombocytopenia often occurs in association with congenital viral infection, especially rubella; cytomegalovirus; protozoal infection, such as toxoplasmosis; syphilis; and perinatal bacterial infection, especially those caused by Gram-negative bacilli. Thrombocytopenia associated with DIC may be responsible for severe spontaneous bleeding. The constellation of marked thrombocytopenia and abnormal abdominal findings is common in necrotizing enterocolitis and other causes of necrotic bowel. Thrombocytopenia in an ill child requires a prompt search for viral and bacterial pathogens.

Antibody-mediated thrombocytopenia in the newborn occurs because of transplacental transfer of maternal antibodies directed against fetal platelets. Neonatal alloimmune thrombocytopenic purpura (NATP) is caused by the development of maternal antibodies against antigens present on fetal platelets that are shared with the father and recognized as foreign by the maternal immune system. This is the platelet equivalent of Rh disease of the newborn. The incidence of NATP is 1/4,000–5,000 live births. The clinical manifestations of NATP include fetal thrombocytopenia. In mothers who have had splenectomy for severe thrombocytopenia before delivery appears to predict a higher risk of fetal thrombocytopenia.

**Treatment** includes prenatal administration of corticosteroids to the mother and administration of IVIG and sometimes corticosteroids to the infant after delivery. Thrombocytopenia in an infant, whether a result of NATP or maternal ITP, usually resolves within 2-4 mo after delivery. The period of highest risk is the immediate perinatal period.

Two syndromes of congenital failure of platelet production often present in the newborn period. In CAMT, the newborn manifests petechiae and purpura shortly after birth. Findings on physical examination are otherwise normal. Megakaryocytes are absent from the bone marrow. This syndrome is caused by a mutation in the megakaryocyte TPO receptor that is essential for development of all hematopoietic cell lines. Pancytopenia eventually develops, and hematopoietic stem cell transplantation is curative. TAR syndrome consists of thrombocytopenia that presents in early infancy, with bilateral radial anomalies of variable severity, ranging from mild changes to marked limb shortening. Thumbs are present. In many such individuals, there are also other skeletal abnormalities of the lower extremities. Intolerance to cow’s milk formula is present in 50% of patients. TAR syndrome frequently remits over the 1st few yr of life (see Chapter 484.8) (see Fig. 484–4).

**Bibliography is available at Expert Consult.**

### 484.10 Thrombocytopenia from Acquired Disorders Causing Decreased Production

**J. Paul Scott and Veronica Flood**

Disorders of the bone marrow that inhibit megakaryopoiesis usually affect RBC and WBC production. Infiltrative disorders, including malignancies, such as acute lymphocytic leukemia, histiocytosis, lymphomas, and storage disease, usually cause either abnormalities on physical examination (lymphadenopathy, hepatosplenomegaly, or masses) or abnormalities of the WBC count, or anemia. Aplastic processes may present as isolated thrombocytopenia, although there are usually clues on the CBC (leukopenia, neutropenia, anemia, or macrocytosis). Children with constitutional aplastic anemia (Fanconi anemia) often have abnormalities on examination, including radial anomalies, other skeletal anomalies, short stature, microcephaly, and hyperpigmentation. Bone marrow examination should be performed when thrombocytopenia is associated with abnormalities found on physical examination or on examination of the other blood cell lines.

### 484.11 Platelet Function Disorders

**J. Paul Scott**

Bleeding time and the platelet function analyzer (PFA-100) are the only commonly available tests to screen for abnormal platelet function. Bleeding time measures the interaction of platelets with the blood vessel wall and thus is affected by both platelet count and platelet function. The predictive value of bleeding time is problematic because bleeding time is dependent on a number of other factors, including the skill of the technician and the cooperation of the patient, often a challenge in the infant or young child. A normal bleeding time does not rule out a mild platelet function defect in a clinically symptomatic individual. The PFA-100 measures platelet adhesion and aggregation in whole blood at high shear when the blood is exposed to either
Bibliography
Bibliography

collagen-epinephrine or collagen-ADP. Results are reported as the closure time measured in sec. Many clinical laboratories have replaced bleeding time with the use of the PFA-100. Both the PFA-100 and bleeding time are sensitive to moderate/severe von Willebrand disease and platelet dysfunction. Both are variably insensitive to mild platelet function abnormalities and mild von Willebrand disease. The use of the PFA-100 as a screening test remains controversial and, like the bleeding time, lacks specificity. Bleeding time is the only commonly available test to assess platelet-vessel wall interaction. For patients with a positive history of bleeding suggestive of von Willebrand disease or platelet dysfunction, specific VWF testing and platelet function studies should be done, irrespective of the results of the bleeding time or PFA-100.

Platelet function in the clinical laboratory is currently measured using platelet aggregometry. In the aggregometer, agonists, such as collagen, ADP, ristocetin, epinephrine, arachidonic acid, and thrombin (or the thrombin receptor peptide), are added to platelet-rich plasma, and the clumping of platelets over time is measured by an automated machine. At the same time, other instruments measure the release of granular contents, such as ATP, from the platelets after activation. The ability of platelets to aggregate and their metabolic activity can be assessed simultaneously. When a patient is being evaluated for possible platelet dysfunction, it is critically important to exclude the presence of other exogenous agents and to study the patient, if possible, off all medications for 2 wk. Further evaluation using flow cytometric analysis or molecular testing are often necessary to make a more definitive diagnosis.

### 484.12 Acquired Disorders of Platelet Function

**J. Paul Scott**

A number of systemic illnesses are associated with platelet dysfunction, most commonly, liver disease, kidney disease (uremia), and disorders that trigger increased amounts of fibrin degradation products. These disorders frequently cause prolonged bleeding time and are often associated with other abnormalities of the coagulation mechanism. The most important element of management is to treat the primary illness. If treatment of the primary process is not feasible, infusions of desmopressin have been helpful in augmenting hemostasis and correcting bleeding time. In some patients, transfusions of platelets and/or cryoprecipitate have also been helpful in improving hemostasis.

Many drugs alter platelet function. The most commonly used drug in adults that alters platelet function is acetylsalicyclic acid (aspirin). Aspirin irreversibly acetylates the enzyme cyclo-oxygenase, which is critical in the formation of thromboxane $\Delta_2$. Aspirin usually causes moderate platelet dysfunction that becomes more prominent if there is another abnormality of the hemostatic mechanism. In children, commonly used drugs that affect platelet function include other nonsteroidal antiinflammatory drugs, valproic acid, and high-dose penicillin. Specific agents to inhibit platelet function therapeutically include those that block the platelet ADP receptor (clopidogrel) and $\alpha$IIb-$\beta$3 receptor antagonists, as well as aspirin.

### 484.13 Congenital Abnormalities of Platelet Function

**J. Paul Scott**

Severe platelet function defects usually present with petechiae and purpura shortly after birth, especially after vaginal delivery. Defects in the platelet GPIb complex (the VWF receptor) or the $\alpha$IIb-$\beta$3 complex (the fibrinogen receptor) cause severe congenital platelet dysfunction. The Bernard-Soulier syndrome, a severe congenital platelet function disorder, is caused by absence or severe deficiency of the VWF receptor (GPIb complex) on the platelet membrane. This syndrome is characterized by thrombocytopenia, with giant platelets and markedly prolonged bleeding time (>20 min) or PFA-100 closure time. Platelet aggregation tests show absent ristocetin-induced platelet aggregation, but normal aggregation to all other agonists. Ristocetin induces the binding of VWF to platelets and agglutinates platelets. Results of studies of VWF are normal. The GPIb complex interacts with the platelet cytoskeleton; a defect in this interaction is believed to be the cause of the large platelet size. Bernard-Soulier syndrome is inherited as an autosomal recessive disorder. Genetic mutations causing Bernard-Soulier syndrome are usually identified in the genes forming the GPIb complex of glycoproteins Ibα, Ibβ, V, and IX.

**Glanzmann thrombasthenia** is a congenital disorder associated with severe platelet dysfunction that yields prolonged bleeding time and a normal platelet count. Platelets have normal size and morphologic features on the peripheral blood smear, and closure times for PFA-100 or bleeding time are markedly abnormal. Aggregation studies show normal or absent aggregation with all agonists used except ristocetin, because ristocetin agglutinates platelets and does not require a metabolically active platelet. This disorder is caused by deficiency of the platelet fibrinogen receptor $\alpha$IIb-β3, the major integrin complex on the platelet surface that undergoes conformational changes by inside-out signaling when platelets are activated. Fibrinogen binds to this complex when the platelet is activated and causes platelets to aggregate. Caused by identifiable mutations in the genes for $\alpha$IIb or $\beta$3, this disorder is inherited in an autosomal recessive manner. For both Bernard-Soulier syndrome and Glanzmann thrombasthenia, the diagnosis is confirmed by flow cytometric analysis of the patient’s platelet glycoproteins.

Hereditary deficiency of platelet storage granules occurs in 2 well-characterized but rare syndromes that involve deficiency of intracytoplasmic granules. Dense body deficiency is characterized by absence of the granules that contain ADP, ATP, Ca2+, and serotonin. This disorder is diagnosed by the finding that ATP is not released on platelet aggregation studies and ideally is characterized by electron microscopic studies. Gray platelet syndrome is caused by the absence of platelet $\alpha$ granules, resulting in large platelets that are large and appear gray on Wright stain of peripheral blood. In this rare syndrome, aggregation and release are absent with most agonists other than thrombin and ristocetin. Electron microscopic studies are diagnostic.

### OTHER HEREDITARY DISORDERS OF PLATELET FUNCTION

Abnormalities in the pathways of platelet signaling/activation and release of granular contents cause a heterogeneous group of platelet function defects that are usually manifested as increased bruising, epistaxis, and/or menorrhagia. Symptoms may be subtle and are often made more obvious by high-risk surgery, such as tonsillectomy or adenoidectomy, or by administration of nonsteroidal antiinflammatory drugs. In the laboratory, bleeding time is variable and closure time as measured by the PFA-100 is frequently, but not always, prolonged. Platelet aggregation studies show deficient aggregation with 1 or 2 agonists and/or abnormal release of granular contents.

The formation of thromboxane from arachidonic acid after the activation of phospholipase A2 is critical to normal platelet function. Deficiency or dysfunction of enzymes, such as cyclo-oxygenase and thromboxane synthase, which metabolize arachidonic acid, causes abnormal platelet function. In the aggregometer, platelets from such patients do not aggregate in response to arachidonic acid.

The most common platelet function defects are those characterized by variable bleeding time/PFA closure times and abnormal aggregation with 1 or 2 agonists, usually ADP and/or collagen. These patients have normal aggregation with thrombin receptor peptide. Some of these individuals have only decreased release of ATP from intracytoplasmic granules; the significance of this finding is debated.

### TREATMENT OF PATIENTS WITH PLATELET DYSFUNCTION

Successful treatment depends on the severity of both the diagnosis and the hemorrhagic event. In all but severe platelet function defects, desmopressin 0.3 µg/kg IV may be used for mild to moderate bleeding...
episodes. In addition to its effect on stimulating levels of VWF and factor VIII, desmopressin corrects bleeding time and augments hemo-

stasis in many individuals with mild to moderate platelet function
defects. For individuals with Bernard-Soulier syndrome or Glanzmann
thrombasthenia, platelet transfusions of 1 unit/5-10 kg corrects the
defect in hemostasis and may be lifesaving. Rarely, antibodies develop
to the deficient platelet protein, rendering the patient refractory to the
transfused platelets. In such patients, the off-label use of recombinant
factor VIIa has been effective, and this treatment is undergoing clinical
trials. In both conditions, hematopoietic stem cell transplantation has
been curative.

Bibliography is available at Expert Consult.

**484.14 Disorders of the Blood Vessels**

*J. Paul Scott*

Disorders of the vessel walls or supporting structures mimic the find-
ings of a bleeding disorder although coagulation studies are usually
normal. The findings of petechiae and purpuric lesions in such patients
are often attributable to an underlying vasculitis/vasculopathy. Skin
biopsy can be particularly helpful in elucidating the type of vascular
pathology.

**HENOCH-SCHÖNLEIN PURPURA**

See Chapter 167.1.

**EHLERS-DANLOS SYNDROME**

See Chapter 659.

**OTHER ACQUIRED DISORDERS**

Scurvy, chronic corticosteroid therapy, and severe malnutrition are
associated with “weakening” of the collagen matrix that supports the
blood vessels. Therefore, these factors are associated with easy bruising,
and particularly in the case of scurvy, bleeding gums and loosening of
the teeth. Lesions of the skin that initially appear to be petechiae and
purpura may be seen in vasculitic syndromes, such as SLE.

ANATOMY

The splenic precursor is recognizable by 5 wk of gestation. At birth, the spleen weighs approximately 11 g. Thereafter, it enlarges until puberty, reaching an average weight of 135 g, and then diminishes in size during adulthood. Approximately 15% of patients will have an accessory spleen. The major splenic components are a lymphoid compartment (white pulp) and a filtering system (red pulp). The white pulp consists of periarterial lymphatic sheaths of T lymphocytes with embedded germinal centers containing B lymphocytes. The red pulp has a skeleton of fixed reticular cells, mobile macrophages, partially collapsed endothelial passages (cords of Billroth), and splenic sinuses. A marginal zone rich in dendritic (antigen-presenting) cells separates the red pulp from the white pulp. The splenic capsule contains smooth muscle and contracts in response to epinephrine. Approximately 10% of the blood delivered to the spleen flows rapidly through a closed vascular network. The other 90% flows more slowly through an open system (the splenic cords), where it is filtered through 1-5 µm slits before entering the splenic sinuses.

FUNCTION

The unique anatomy and blood flow of the spleen enable it to perform reservoir, filtering, and immunologic functions. The spleen receives 5-6% of the cardiac output, but normally contains only 25 mL of blood. It can retain much more when it enlarges leading to cytopenias. Hematopoiesis is a major splenic function at 3-6 mo of fetal life but then disappears. Splenic hematopoiesis can be resumed in patients with myelofibrosis or severe hemolytic anemia. Factor VIII and one-third of the circulating platelet mass are sequestered in the spleen and can be released by stress or epinephrine injection. Thrombocytosis and leukocytosis occur with loss of the splenic reservoir function. A high platelet count after the loss of splenic function or splenectomy is not associated with an increased risk of thrombosis in children.

Slow blood flow past macrophages and through small openings in the sinus walls facilitates the filtering functions of the spleen. Excess membrane is removed from young red blood cells (RBCs); loss of this function is characterized by target cells, poikilocytosis, and decreased osmotic fragility. The spleen is the primary site for destruction of old RBCs; this function is assumed by other reticuloendothelial cells after splenectomy. The spleen also removes damaged/abnormal red cells (such as spherocytes and antibody-coated RBCs) and damaged/senescent platelets. Intracytoplasmic inclusions may be removed from RBCs without cell lysis. Functional or anatomic hyposplenia is characterized by continued circulation of cells containing nuclear remnants (Howell-Jolly bodies), denatured hemoglobin (Heinz bodies), and other debris in RBCs. This debris may appear as “pits” on indirect microscopy.

The spleen plays a large role in host defense against infection. The spleen is the largest lymphoid organ in the body and contains nearly half of the body’s total immunoglobulin-producing B lymphocytes. The spleen processes foreign material to stimulate production of opsonizing antibody. Properdin and tuftsin are also produced in the spleen. Thus, young (nonimmune) or hyposplenic individuals are at increased risk for sepsis caused by pneumococci and other encapsulated bacteria. The spleen can also use phagocytosis to trap and destroy intracellular parasites. The spleen has a minor role in antibody response to intramuscularly or subcutaneously injected antigens but is required for early antibody production after exposure to intravenous antigens. The spleen may be an important site of antibody production in immune thrombocytopenia purpura.

CLINICAL MANIFESTATIONS

A soft, thin spleen is palpable in 15% of neonates, 10% of normal children, and 5% of adolescents. In most individuals, the spleen must be 2-3 times its normal size before it is palpable. The spleen is best examined when standing on the right side of a supine patient by

Differential Diagnosis

Table 486-1 lists specific causes of splenomegaly. A thorough history with a focus on systemic complaints (fever, night sweats, malaise, weight loss) and a complete physical exam (with special attention to adenopathy), in combination with a complete blood count and careful review of the peripheral smear can help guide diagnosis.

Pseudosplenomegaly

Abnormally long mesenteric connections may produce a wandering or pototic spleen. An enlarged left lobe of the liver, a left upper quadrant mass, or a splenic hematoma may be mistaken for splenomegaly.
Splenic cysts may contribute to splenomegaly or mimic it; these may be congenital (epidermoid) or acquired (pseudocyst) after trauma or infarction. Cysts are usually asymptomatic and are found on radiologic evaluation. Splenosis after splenic rupture or an accessory spleen (present in 15% of normal individuals) may also mimic splenomegaly; most are not palpable. The syndrome of congenital polysplenism includes cardiac defects, left-sided organ anomalies, bilobed lungs, biliary atresia, and pseudosplenomegaly (see Chapter 431.11).

**Hypersplenism**

Increased splenic function (sequestration or destruction of circulating cells) can result in peripheral blood cytopenias (thrombocytopenia, neutropenia, anemia), increased bone marrow activity, and splenomegaly. It is usually secondary to another disease and may be cured by treatment of the underlying condition or, if absolutely necessary, moderated by splenectomy.

**Congestive Splenomegaly (Banti Syndrome)**

Splenomegaly may result from obstruction in the hepatic, portal, or splenic veins leading to hypersplenism. Wilson disease (see Chapter 357.2), galactosemia (see Chapter 87.2), biliary atresia (see Chapter 356.1), and α₁-antitrypsin deficiency (see Chapter 357) may result in hepatic inflammation, fibrosis, and vascular obstruction. Congenital abnormalities (absence or hypoplasia) of the portal or splenic veins may cause vascular obstruction. Septic omphalitis or thrombophlebitis (spontaneous or as a result of umbilical venous catheterization in neonates) may result in secondary obliteration of these vessels. Splenic venous flow may be obstructed by masses of sickled erythrocytes leading to infarction. When the spleen is the site of vascular obstruction, splenectomy cures hypersplenism. However, since obstruction usually is in the hepatic or portal systems, portacaval shunting may be more helpful, because both portal hypertension and thrombocytopenia contribute to variceal bleeding.

Bibliography

**HYPOSPLENISM**

Congenital absence of the spleen is associated with complex cyanotic heart defects, dextrocardia, bilateral trilobed lungs, and heterotopic abdominal organs (Ivemark syndrome; see Chapter 431.11). Splenic function is usually normal in children with congenital polysplenia. Functional hyposplenism may occur in normal neonates, especially premature infants. Children with sickle cell hemoglobinopathies (see Chapter 462.1) may have splenic hypofunction as early as 6 mo of age. Initially, this is caused by vascular obstruction, which can be reversed with red blood cell (RBC) transfusion or hydroxyurea. The spleen eventually autoinfarcts and becomes fibrotic and permanently non-functional. Functional hyposplenism may also occur in malaria (see Chapter 288), after irradiation to the left upper quadrant, and when the reticuloendothelial function of the spleen is overwhelmed (as in severe hemolytic anemia or metabolic storage disease). Splenic hypofunction has been reported occasionally in patients with autoimmune diseases (i.e., rheumatoid arthritis, lupus, sarcoidosis), nephritis, inflammatory bowel disease, celiac disease, chronic hepatitis, Pearson syndrome, Fanconi anemia, and graft-versus-host disease) (Table 487-1).

Splenic hypofunction is characterized by RBC inclusions in peripheral blood smears (Howell-Jolly bodies or Heinz bodies), “pits” on interference microscopy, and poor uptake of technetium or other spleen scans (Table 487-2, Fig. 487-1). Reduced immunoglobulin M memory B cells may also be detected and is a risk factor for overwhelming sepsis. Patients with functional hyposplenism or asplenia are at increased risk for sepsis from encapsulated bacteria and benefit from antibiotic prophylaxis.

**SPLENIC TRAUMA**

Injury to the spleen may occur with abdominal trauma. Small splenic capsular tears may cause abdominal or referred left shoulder pain as a result of diaphragmatic irritation by blood. Larger tears result in more severe blood loss, with similar pain and signs of hypovolemic shock. Previously enlarged spleens (as in patients with infectious mononucleosis) are more likely to rupture with minor trauma. Patients with splenomegaly should avoid contact sports and other activities that increase the risk of splenic trauma. CT scan with IV contrast is the best imaging modality to assess splenic trauma.

**Treatment** of a small capsular injury should include careful observation with attention to changes in vital signs or abdominal findings, serial hemoglobin determinations, and the availability of prompt surgical intervention if a patient’s condition deteriorates (see Chapter 72).

Figure 487-1 Characteristic pitted erythrocytes. A pitted erythrocyte is recognizable on phase-interference microscopy by the characteristic “pit” on the cell membrane (arrows). (From Di Sabatino A, Carsetti R, Corazza GR. Post-splenectomy and hyposplenic states, Lancet 378(9785):86-97, 2011, Fig. 2.)

RBC transfusion requirements should be minimal (<25 mL/kg/48 hr). These patients are usually hospitalized for 10-14 days and have their activities restricted for months. Laparotomy, with or without splenectomy, is indicated for more marked abdominal bleeding, in patients who have clinical instability or deterioration, or when other organ damage is suspected. Partial splenectomy and splenic repair should be substituted for total splenectomy when feasible to maintain some splenic immune function.

**Splenectomy**

Splenectomy should be limited to specific indications where medical therapy is (or has been) ineffective. These include traumatic splenic rupture, anatomic defects, severe transfusion dependent hemolytic anemia, immune cytopenias, metabolic storage diseases, and secondary hypersplenism. The major long-term risk of splenectomy is sudden, overwhelming post-splenectomy infections (sepsis or meningitis). This risk is especially high in children younger than 5 yr at the time of surgery. The risk of sepsis is less when splenectomy is performed for trauma, RBC membrane defects, and immune thrombocytopenia (2-4%) than when there is sickle cell anemia, thalassemia, or a preexisting immune deficiency (Wiskott-Aldrich syndrome, Hodgkin disease) or reticuloendothelial blockade (storage disease, severe hemolytic anemia) (8-30%). The overall risk is 2-5 per 1,000 asplenic patient years, with a lifelong risk of overwhelming post-splenectomy infections of 5%; more than half occur within 2 yr after splenectomy, although

the risk remains lifelong. The use of laparoscopic splenectomy has decreased surgical morbidity and hospitalization time.

Encapsulated bacteria, such as *Streptococcus pneumoniae* (>60% of cases), *Haemophilus influenzae*, and *Neisseria meningitidis*, account for >80% of cases of post-splenectomy sepsis. Because the spleen is responsible for filtering the blood and for early antibody responses, sepsis (with or without meningitis) can progress rapidly, leading to death within 12-24 hr of onset. Febrile splenectomized patients should be evaluated and treated promptly with antibiotics to cover the organisms previously mentioned. This treatment should be initiated at home if access to definitive medical care will be delayed. A broad-spectrum cephalosporin (cefotaxime or ceftriaxone) is recommended until specific antibiotic susceptibility and presence or absence of meningitis is known. Vancomycin (to cover penicillin-resistant pneumococci) should be initiated, depending on the illness severity and susceptibilities of pneumococci at the institution. Splenectomized patients are also at increased risk for contracting protozoal infections, such as malaria and babesiosis. Serious infection may occur after an animal bite (particularly dogs) and is due to *Capnocytophaga canimorsus* or *C. cynodegmi*. Prophylactic antibiotics should be given after a bite to potentially prevent sepsis caused by these organisms (see Chapter 724).

**Preoperative, intraoperative, and postoperative** management may decrease the risk of post-splenectomy infection. It is important to be certain of the need for splenectomy and, if possible, to postpone the operation until the patient is 5 yr of age or older. Pneumococcal, meningococcal, and *H. influenzae* conjugate vaccines given at least 14 days before splenectomy may reduce post-splenectomy sepsis. The 7-valent pneumococcal polysaccharide-protein conjugate vaccine (PCV7) was replaced with the 13-valent pneumococcal polysaccharide-protein conjugate vaccine (PCV13). Thus, depending on what primary pneumococcal vaccine was given, a single dose of PCV13 may be recommended. In addition, the 23-valent pneumococcal polysaccharide vaccine (Pneumovax) should be given at age ≥2 yr and a second dose 5 yr later. Yearly influenza vaccine should also be given as influenza infection is a risk factor for secondary pneumococcal infections. Prophylaxis with oral penicillin VK (125 mg twice daily for children younger than 5 yr; 250 mg twice daily for children 5 yr or older) should be given until at least 5 yr of age and for at least 2 yr after splenectomy. Although the greatest risk is in the immediate postoperative period, reports of deaths occurring years after splenectomy suggest that the risk (and the need for prophylaxis) may be lifelong. Lifelong prophylaxis should be strongly considered in patients who have had an invasive pneumococcal infection or who have an underlying immune deficiency. In children with sickle cell disease, penicillin prophylaxis should be started as soon as the diagnosis is made.
Prophylaxis may be continued into adulthood for higher-risk patients, including those with a history of pneumococcal sepsis, but effectiveness in this older group has not been well documented.

In patients with traumatic injury, splenic repair or partial splenectomy should be considered in an attempt to preserve splenic function. Partial splenectomy or partial splenic embolization may be sufficient to ameliorate some forms of hemolytic anemia. Up to 50% of children whose spleen is removed because of trauma have spontaneous splenosis; surgical splenosis (distributing small pieces of spleen throughout the abdomen) may decrease the risk of sepsis in patients whose splenectomy is necessitated by trauma. However, in both of these settings, the splenic tissue that regrows frequently has poor function.

In addition to postsplenectomy sepsis, splenectomized patients may be at risk for thromboembolic complications, including arterial and venous thrombosis and pulmonary hypertension. These findings have been reported regardless of the underlying reason for splenectomy and the postsplenectomy platelet count. Proposed mechanisms include loss of filtering function of the spleen, allowing abnormal RBCs to remain in the circulation and activate the coagulation cascade. Portal vein thrombosis has been reported as a complication of laparoscopic splenectomy.

Chapter 487 - Hyposplenism, Splenic Trauma, and Splenectomy

**Bibliography**
Anatomy and Function of the Lymphatic System

Richard L. Tower and Bruce M. Camitta

The lymphatic system participates in many biologic processes, including fluid homeostasis, absorption of dietary fat, and initiation of specific immune responses. This system includes circulating lymphocytes, lymphatic vessels, lymph nodes, spleen, tonsils, adenoids, Peyer patches, and thymus. Lymph, an ultrafiltrate of blood, is collected by lymphatic capillaries that are present in all organs except the brain, bone marrow, retina, cartilage, epidermis, hair, and nails. These join to form progressively larger vessels that drain regions of the body. The lymphatic vessels carry lymph to the lymph nodes, where it is filtered through sinuses, particulate matter and infectious organisms are phagocytosed, and antigens are presented to surrounding lymphocytes. These actions stimulate antibody production, T-cell responses, and cytokine secretion (see Chapter 123). Lymph is ultimately returned to the intravascular circulation.

The composition of lymph can vary with the site of lymph drainage. It is usually clear, but lymph drained from the intestinal tract may be milky (chylous) because of the presence of fats. The protein content is intermediate between that of an exudate and a transudate. The protein level may be increased with inflammation and in lymph drained from the liver or intestines. Lymph also contains variable numbers of lymphocytes and antigen-presenting cells.

Embryonic lymphatic development (primary lymphangiogenesis) proceeds from the stage of lymphatic competence, through lymphatic commitment, specification, coalescence, and maturation. Secondary lymphangiogenesis occurs in the settings of wound healing and inflammation. Many genes are crucial to normal lymphatic development and function, including Prox1, vascular endothelial growth factor–C (VEGF-C), and vascular endothelial growth factor receptor–3 (VEGFR-3).

Bibliography is available at Expert Consult.
Bibliography

Abnormalities of the lymph vessels may be congenital or acquired. Signs and symptoms result from increased lymphatic tissue mass or from leakage of lymph. **Lymphangiectasia** is dilatation of the lymphatics. Pulmonary lymphangiectasia causes respiratory distress (see Chapter 395.6). Involvement of the intestinal lymphatics causes hypoproteinemia and lymphocytopenia secondary to loss of lymph into the intestines (see Chapter 338). Therapy includes minimizing the hydrostatic pressure in the lymphatic system. Reducing dietary intake of long-chain fatty acids and substituting medium-chain triglycerides may accomplish this goal. If unsuccessful, octreotide or propranolol may be tried. **Lymphangioma** is a congenital lymphatic malformation, usually detected by age 2 yr. **Lymphangioma circumscriptum** is defined as the presence of many small, superficial lymphangiomas. Deeper lymphangiomas are classified as either **cavernous lymphangiomas** or **cystic hygromas**.

**Lymphangiomatosis** is the presence of multiple or disseminated malformations. Some of these lesions also have a hemangiomatous component (see Chapter 505). Thoracic lymphangiomatosis presents with chylothorax, a mass, or with pulmonary infiltrates. Associated features include bone, skin, and splenic lesions. The disorder is either diffuse or multifocal and is differentiated from lymphangiectasia by the presence of complex anastomosis of vessels with dilation rather than simple dilation of preexisting lymphatic capillaries. Emergent surgical treatment is infrequently necessary due to mass effects. Most lesions may be observed for 18-24 mo to assess for involution. Surgery is effective for superficial lesions, but there is a high incidence of recurrence when used for deeper lesions. Intrallesional sclerosing with OK-432, a streptococcal derivative, has been used successfully in selected patients. Other sclerotherapy agents include pure ethanol and bleomycin. Macrocystic lesions appear to respond better than microcystic lymphangiomas to sclerotherapy. Radiofrequency ablation has been used for lymphatic lesions of the tongue. **Lymphatic dysplasia** may cause multisystem problems. These include lymphedema, chyloascites, chylothorax, and lymphangiomatosis of the bone, lung, or other sites.

**Lymphangioleiomyomatosis** is characterized by proliferation of lymphatic endothelial cells and smooth muscle cells in the lungs, leading to airway and lymphatic obstruction, cyst formation, pneumothorax, and respiratory failure. It may initially be mistaken for asthma. Lymphangioleiomyomatosis occurs in young women and is also associated with mutations in the tuberous sclerosis tumor-suppressor gene TSC2 in one-third of cases. Sirolimus (rapamycin) stabilizes lung function, reduces symptoms, and improves life quality; lung transplantation may be required.

**Lymphedema**, a localized swelling caused by impaired lymphatic flow, can be congenital or acquired. Congenital lymphedema may be found in Turner syndrome, Noonan syndrome, and the autosomal dominantly inherited Milroy disease, among other chromosomal abnormalities. Several families with Milroy disease have mutations in the vascular endothelial growth factor receptor-3 gene (**VEGFR-3**).
Autosomal recessive and X-linked inheritance has also been reported. Mutations in *GJC2* are associated with hereditary lymphedema. **Lymphedema praecox** (Meige disease) causes progressive lower extremity edema, usually in females during the peripubertal period or pregnancy. **Hypotrichosis-lymphedema-telangiectasia syndrome**, which has dominant and recessive inheritance patterns, has been linked to mutations in *SOX18*. Lymphedema has also been found in association with intestinal lymphangiectasia, cerebrovascular malformation, ptosis, yellow dystrophic nails, distichiasis, and cholestasis. Mutations in *FOXC2* are associated with lymphedema-distichiasis syndrome, which has a pubertal onset of lymphedema. Mutations in *CCBE1*, *PTPN14*, and *GATA2* are associated with Hennekam lymphangiectasia-lymphedema syndrome (lymphedema of the extremities, intestinal lymphangiectasia, mental retardation), lymphedema-choanal atresia syndrome, and Emberger syndrome (lymphedema of the lower extremities and genitalia, deafness, immune dysfunction, and warts), respectively.

Acquired obstruction of the lymphatics can result from tumor, post-irradiation fibrosis, and postinflammatory scarring. **Filaria**sis is an important cause of lymphedema in Africa, Asia, and Latin America; of the estimated 120 million infected persons, approximately 40 million (primarily older adolescents and adults) are believed to have lymphedema or hydrocele. Injury to the major lymphatic vessels can cause collection of lymph fluid in the abdomen (chylous ascites) or chest (chylothorax). Untreated lymphedema can be disabling and is associated with immune dysfunction, inflammation, fibrosis, adipose tissue overgrowth, and **lymphangiosarcoma**. Current treatment modalities attempt to reduce localized swelling through massage, exercise, and compression. No drugs have been proven efficacious. Diuretic use should be avoided. The recently discovered gene mutations provide potential for targeted therapy, including gene therapy. Autologous lymph node transplantation and use of growth factors to stimulate lymphangiogenesis may also be on the horizon for treatment of lymphedema.

**Lymphangitis** is an inflammation of the lymphatics that drain an area of infection. Tender, erythematous streaks extend proximally from the infected area. Regional nodes may also be tender. Group A streptococci and *Staphylococcus aureus* are the most frequent pathogens and therapy should include antibiotics that treat these organisms.

Lymphadenopathy

Richard L. Tower and Bruce M. Camitta

Palpable lymph nodes are common in pediatrics. Lymph node enlargement is caused by proliferation of normal lymphoid elements or by infiltration with malignant or phagocytic cells. In most patients, a careful history and a complete physical examination suggest the proper diagnosis.

**DIAGNOSIS**

Is the mass a lymph node? Nonlymphoid masses (cervical rib, thyroglossal cyst, branchial cleft cyst or infected sinus, cystic hygroma, goiter, sternomastoid muscle tumor, thyroiditis, thyroid abscess, neurofibroma) occur frequently in the neck and less often in other areas. Is the node enlarged? Lymph nodes are not usually palpable in the newborn. With antigenic exposure, lymphoid tissue increases in volume. They are not considered enlarged until their diameter exceeds 1 cm for cervical and axillary nodes and 1.5 cm for inguinal nodes. Other lymph nodes usually are not palpable or visualized with plain radiographs. What are the characteristics of the node? Acutely infected nodes are usually tender. There may also be erythema and warmth of the overlying skin. Fluctuance suggests abscess formation. Tuberculous nodes may be matted. With chronic infection, many of these signs are not present. Tumor-bearing nodes are usually firm and nontender and may be matted or fixed to the skin or underlying structures.

Is the lymphadenopathy localized or generalized? Generalized adenopathy (enlargement of >2 noncontiguous node regions) is caused by systemic disease (Table 490-1) and is often accompanied by abnormal physical findings in other systems. In contrast, regional adenopathy is most frequently the result of infection in the involved node and/or its drainage area (Table 490-2). When caused by infectious agents other than bacteria, adenopathy may be characterized by atypical anatomic areas, a prolonged course, a draining sinus, lack of prior pyogenic infection, and unusual clues in the history (cat scratches, tuberculosis exposure, venereal disease). A firm, fixed node should always raise the question of malignancy, regardless of the presence or absence of systemic symptoms or other abnormal physical findings.

**TREATMENT**

Evaluation and treatment of lymphadenopathy is guided by the probable etiologic factor, as determined from the history and physical examination. Many patients with cervical adenopathy have a history compatible with viral infection and need no intervention. If bacterial infection is suspected, antibiotic treatment covering at least streptococci and staphylococci is indicated. Those who do not respond to oral antibiotics, as demonstrated by persistent swelling and fever, require IV antistaphylococcal antibiotics. If there is no response in 1-2 days, or if there are signs of airway obstruction or significant toxicity, ultrasound, CT, or MRI of the neck should be obtained. If pus is present, it may be aspirated, with CT or ultrasound guidance, or if it is extensive, may require incision and drainage. Gram stain and culture of the pus should be obtained. The sizes of involved nodes should be documented before treatment. Failure to decrease in size within 10-14 days also suggests the need for further evaluation. This may include a complete blood cell

### 490.1 Kikuchi-Fujimoto Disease (Histiocytic Necrotizing Lymphadenitis)

**Richard L. Tower and Bruce M. Camitta**

Kikuchi-Fujimoto disease is a rare, usually self-limiting disease that was originally reported in patients of Asian heritage. Cases are now described in all ethnic groups. Familial cases have been reported. Presentation is varied and may include fever of unknown origin, but more often, it occurs in children 8-16 yr of age as firm unilateral posterior cervical adenitis, fever, malaise, elevated erythrocyte sedimentation rate, atypical lymphocytosis, and leukopenia. Nodes range in size from only 0.5-6.0 cm, are painful or tender in only 50% of cases, may be multiple, and must be differentiated from lymphoma. Node involvement may occasionally be bilateral or present in axillary or supraclavicular nodes.

The etiology is unknown, although viral and bacterial causes have been suggested. Growing evidence supports an abnormal immune response; the diagnosis is made by lymph node biopsy. Histologic features include necrosis with karyorrhexis, a histiocytic infiltrate, crescentic plasmacytoid mononuclear and an absence of neutrophils. The disease is self-limiting and usually spontaneously resolves within 6 mo, although relapses may occur up to 16 yr later. Therapy with systemic steroids is reserved for cases with severe symptoms. Rarely, the disease has been fatal. Many autoimmune diseases have been associated with Kikuchi-Fujimoto disease, most commonly systemic lupus erythematosus. The differential diagnosis includes lymphoma, tuberculosis, and systemic lupus erythematosus.

### 490.2 Sinus Histiocytosis with Massive Lymphadenopathy (Rosai-Dorfman Disease)

**Richard L. Tower and Bruce M. Camitta**

This uncommon, benign, and usually self-limiting disease has a worldwide distribution but is more common in Africa and the Caribbean. The etiology is unknown, but immune dysfunction is suspected. Patients present with massive bilateral, painless, mobile cervical adenopathy, along with fever, leukocytosis, high erythrocyte sedimentation...
Bibliography

Bibliography

rate, and polyclonal elevation of immunoglobulin G (hypergammaglobulinemia). Night sweats and weight loss are common. Autoimmune hemolytic anemia is an uncommon associated finding. It rarely occurs at birth or in siblings, and males are affected more often than females.

Other nodal chains may be involved. Extranodal involvement occurs in 40% of cases. Soft-tissue involvement of all organ systems has been reported. The most common sites are the skin, followed by the nasal cavity and sinuses, palate, orbit, bone, and central nervous system. Occasionally autoantibodies to erythrocytes or synovium may be present. A biopsy that demonstrates pale histiocytes containing engulfed lymphocytes (emperiploisois), and immunoreactivity to S100 protein in large histiocytes, in conjunction with expected clinical features, is diagnostic. The differential diagnosis includes Langerhans cell histiocytosis, myeloproliferative disorders, and lymphoma.

Therapy is usually not needed for this self-limited disease. However, the disease may recur frequently for many years. Life- or organ-threatening disease or exacerbations may respond to prednisone. Refractory cases have been treated with surgical excision or radiation. Rare patients have been treated with immune-modulating therapy, including interferon-α, 2-chlorodeoxyadenosine, imatinib, and rituximab. Therapy with antibiotics and chemotherapy has been unsuccessful.

**Bibliography is available at Expert Consult.**

### 490.3 Castleman Disease

Richard L. Tower and Bruce M. Camitta

Castleman disease is an uncommon lymphoproliferative disease and is also called angiofollicular lymph node hyperplasia. The underlying etiology is unknown, although an association with human herpesvirus 8 has been identified. Human herpesvirus 8 may stimulate excessive production of interleukin 6 (IL-6). The disease usually presents in adolescents or young adults. Enlargement of a single node, most often in the mediastinum or abdomen, is the most common localized presentation. Some patients may have fever, night sweats, weight loss, and fatigue. Management includes surgery and/or radiation therapy.

**Multicentric Castleman disease** is a systemic lymphoproliferative disorder that causes lymphadenopathy, hepatosplenomegaly, fever, anemia, overexpression of IL-6, and polyclonal hypergammaglobulinemia. Multicentric Castleman disease may be associated with HIV infection, autoimmune disease-associated lymphadenopathy, and POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M-proteins, and skin lesions). Non-Hodgkin lymphoma may be concurrent or may develop as a result of disease progression. There is no standard treatment for multicentric Castleman disease. Therapeutic options include chemotherapy, steroids, monoclonal antibodies to CD20 (rituximab), monoclonal antibodies (siltuximab) to IL-6, anti-IL-6-receptor antibodies (tocilizumab), antiviral agents, and interferon-α. Chemotherapy regimens used for diffuse large B-cell lymphoma and/or rituximab is currently the most common frontline therapies and has achieved durable remissions. Ganciclovir is the most active antiviral agent. Steroids and anti-IL-6 therapies provide symptomatic relief, but symptoms return after stopping therapy.

Bibliography
Bibliography

Cancer in patients younger than 20 yr of age is uncommon, with an age-adjusted annual incidence of 18.7 per 100,000 children ages 0-19 yr, representing only approximately 1% of all new cancer cases in a year in the United States or an estimated 16,600 new cases/yr in 2014. This translates to nearly a 1 in 300 chance of developing cancer by age 20 yr. Although the relative 5 yr survival rates have improved from 61% in 1977 to 83.6% in 2010 in all age groups 0-19 yr (Fig. 491-1), malignant neoplasms remain the leading cause of disease-related (noninjury) mortality (12%) among persons 1-19 yr of age with 1,800-1,900 cancer-related deaths annually in the United States among children and adolescents 0-19 yr of age. The relative contribution of cancer to the overall mortality in infants 0-1 yr old and adolescents 15-19 yr old is lower than for children ages 1-14 yr. The impressive improvements in survival over the past 3.5 decades are attributed primarily to advances in treatment and enrollment in clinical trials for the majority of patients. Multinstitutional cooperative clinical trials investigating novel therapies and investigating ways to improve survival rates even further and to decrease treatment-related long-term complications are ongoing. Because increasingly more patients survive their disease, clinical investigations also are focusing on the quality of life among survivors and the late outcomes of therapy for pediatric and adult survivors of childhood cancer. The National Cancer Institute estimates that in 2010 there were 380,000 persons alive (in all age groups) who had survived childhood cancer, corresponding to 1 in 300 children and adolescents alive in the U.S. population.

Pediatric malignancies differ markedly from adult malignancies in both prognosis and distribution by histology and tumor site. Lymphohematopoietic cancers (i.e., acute lymphoblastic leukemia, myeloid leukemia, Hodgkin and non-Hodgkin lymphomas) account for approximately 40%, central nervous system cancers for approximately 30%, and embryonal tumors and sarcomas for approximately 10% among the broad categories of childhood cancers (Table 491-1). In contrast, epithelial tumors of organs such as lung, colon, breast, and prostate, which are commonly seen among adults, are rare malignancies in children. Incidence patterns in the pediatric age group show 2 peaks: the first in early childhood and the second in adolescence (Fig. 491-2). During the 1st yr of life, embryonal tumors such as neuroblastoma, nephroblastoma (Wilms tumor), retinoblastoma, rhabdomyosarcoma, hepatoblastoma, and medulloblastoma are most common (Figs. 491-3 and 491-4). These tumors are much less common in older children and adults after cell differentiation processes have slowed considerably. Embryonal tumors, acute leukemias, non-Hodgkin lymphomas, and gliomas peak in incidence from 2-5 yr of age. As children age, bone malignancies, Hodgkin disease, gonadal germ cell malignancies (testicular and ovarian carcinomas), and other carcinomas increase in incidence. Adolescence is a transitional period between the common early childhood malignancies and characteristic carcinomas of adulthood (Fig. 491-4). Incidence rates also vary by gender (generally higher in boys vs girls), race/ethnicity (more common in whites), and between countries (data assembled by the International Agency for Research in Cancer in Lyon, France, http://www.iarc.fr). Over the past 35 yr, 1975-2010, there has been some increase in the incidence of children and adolescents diagnosed with cancer particularly in occurrence of leukemia and among adolescents. These variations are not fully understood but likely reflect differences in genetic susceptibility and environmental exposures related to both known and unknown causes and risk factors for cancer (Table 491-2).

Childhood cancer includes a diverse array of malignant tumors, termed “cancers,” and nonmalignant tumors arising from disorders of genetic processes involved in control of cellular growth and development. Although many genetic conditions are associated with increased risks for childhood cancer, such conditions are believed to account for <5% of all occurrences (see Chapter 492). The most notable genetic conditions that impart susceptibility to childhood cancer are neurofibromatosis types 1 and 2, Down syndrome, Beckwith-Wiedemann syndrome, tuberous sclerosis, von Hippel-Lindau disease, xeroderma pigmentosum, ataxia-telangiectasia, neuvus basal cell carcinoma syndrome, and Li-Fraumeni (P53) syndrome. The varying incidence patterns of individual childhood cancers around the world imply additional genetic and epidemiologic risk factors that remain uncharacterized.

Compared with adult epithelial tumors, an extremely small fraction of pediatric cancers appear to be explained by known environmental exposures (see Table 491-2). Ionizing radiation exposure and several chemotherapeutic agents explain only a small number of pediatric cases (see Chapter 718). The association between fetal exposures and pediatric cancer is largely not established, with the exception of maternal diethylstilbestrol intake during pregnancy and subsequent vaginal adenocarcinoma in adolescent daughters. Environmental exposures that have been studied without convincing evidence for a causal role include nonionizing power frequency electromagnetic fields, pesticides, parental occupational chemical exposures, dietary factors, in vitro fertilization, and environmental cigarette smoke. Viruses have been associated with certain pediatric cancers, such as polyomaviruses (BK, JC, SV40) associated with brain cancer and Epstein-Barr virus with non-Hodgkin lymphoma, but the etiologic importance remains unclear. The etiology of cancer in children still is poorly understood, and epidemiology studies demonstrate that the likely mechanisms are multifactorial, possibly resulting from potential interactions between genetic susceptibility traits and environmental exposures. Ongoing studies are investigating the role of polymorphisms of genes encoding enzymes, which function in the activation or metabolism of xenobiotics, protection of cells against oxidative stress, DNA repair, and/or immune modulation.

Curative therapy with chemotherapy, radiation, and/or surgery can adversely affect a child’s development and result in serious long-term medical and psychosocial effects in childhood and adulthood. Potential adverse late effects include subsequent second malignancy, early mortality, infertility, reduced stature, cardiomyopathy, pulmonary fibrosis, osteoporosis, neurocognitive impairment, affective disorders, and altered social functioning. Much has been learned about the incidence of late effects from large multisite cohort studies such as the Childhood Cancer Survivor Study, an ongoing study of medical and psychosocial outcomes in survivors, which has provided data for the development of clinical care guidelines for survivors (http://www.survivorshipguidelines.org).

Given the relative rarity of specific types of childhood cancer and the sophisticated technology and expertise required for diagnosis, treatment, and monitoring of late effects, all children with cancer...

should be treated with standardized clinical protocols in pediatric clinical research settings whenever possible. Promoting such treatment, the Children’s Oncology Group is a multiinstitutional research consortium that facilitates cooperative clinical, biologic, and epidemiologic research in more than 200 affiliated institutions in the United States, Canada, and other countries (http://childrensoncologygroup.org/). Coordinated participation in such research trials has been a major factor in the increased survival for many children with cancer. Such ongoing efforts are critical to better understand the etiology of childhood cancers, improve survival for malignancies with a poor prognosis, and maximize the quality of life for survivors.

**Influencing the Incidence of Cancer**

Pediatricians have a unique opportunity to educate children and adolescents, and their parents, regarding means of preventing cancer. There are only a few recognized environmental causes of childhood cancer that can be avoided or counteracted. One example is immunization against hepatitis B, which does decrease the risk of hepatocellular carcinoma in adolescence and adulthood; another is human papillomavirus vaccination, which prevents cervical cancer. Associations between cumulative radiation exposure from common diagnostic radiologic tests such as CT scans and an increased risk of malignancy later in life are of great concern for pediatricians. Guidelines to ensure the safe clinical use of diagnostic imaging are being evaluated (http://www.imagegently.org/). An objective of pediatric medicine is to teach children how to adopt healthy lifestyles to reduce their risk of cancer during adulthood, such as avoiding tobacco, alcohol, high-fat diets, and obesity. The earlier these habits are instilled, the greater the lifelong benefit and the more likely it is to be present and sustained during adulthood.

Bibliography

Cancer is a complex of diseases arising from alterations that can occur in a wide variety of genes. Alterations in normal cellular processes such as signal transduction, cell-cycle control, DNA repair, cellular growth and differentiation, translational regulation, senescence, and apoptosis can result in a malignant phenotype.

GENES INVOLVED IN ONCOGENESIS

Two major classes of genes are implicated in the development of cancer: oncogenes and tumor-suppressor genes. Protooncogenes are cellular genes that are important for normal cellular function and code for various proteins, including transcriptional factors, growth factors, and growth factor receptors. These proteins are vital components in the network of signal transduction that regulate cell growth, division, and differentiation. Protooncogenes can be altered to form oncogenes—genes that, when translated, can result in the malignant transformation of a cell.

Oncogenes can be divided into 5 different classes based on their mechanisms of action. Changes in any of these normal cellular components can result in unchecked cell growth. Some oncogenes code for growth factors that bind to a receptor and stimulate the production of a protein. Other oncogenes code for growth factor receptors. These are proteins on the cell surface. When growth factors bind to a growth factor receptor, they can turn the receptor on or off. Mutational or posttranslational modifications of the receptor can result in a receptor being permanently turned on with consequent unregulated growth.

Signal transducers or effectors make up another class. Signal transducers are responsible for taking the signal from the cell surface receptor to the cell nucleus. NRAS, as described below, is an example of this class of protein. Transcription factors are molecules that bind to specific areas of the DNA and control transcription. MYC, described below, is an example of a transcription factor that results in overstimulation of cell division. The final class of oncogenes interferes with apoptosis. Cells that no longer respond to the signal to die can continue to proliferate.

The 3 main mechanisms by which protooncogenes can be activated include amplification, point mutations, and translocation (Table 492-1). MYC, which codes for a protein that regulates transcription, is an example of a protooncogene that is activated by amplification. Patients with neuroblastoma in which the MYC gene is amplified 10-300-fold have a poorer outcome. Point mutations can also activate protooncogenes. The NRAS protooncogene codes for a guanine nucleotide-binding protein with guanosine triphosphatase activity that is important in signal transduction and is mutated in 25-30% of acute nonlymphocytic leukemias, resulting in a constitutively active protein. The RET protein is a transmembrane tyrosine kinase receptor that is important in signal transduction. A point mutation in the RET gene results in the constitutive activation of a tyrosine kinase, as found in multiple neoplasia syndromes and familial thyroid carcinoma.

The third mechanism by which protooncogenes become activated is by chromosomal translocation. In some leukemias and lymphomas, transcription factor controlling sequences are relocated in front of T-cell receptors or immunoglobulin genes, resulting in unregulated transcription of the genes and leukemogenesis. Chromosomal translocations can also result in fusion genes; transcription of the fusion gene can result in the production of a chimeric protein with new and potentially oncogenic activity. Examples of cancers associated with fusion genes include the childhood solid tumors like Ewing sarcoma [t(11;22)] and alveolar rhabdomyosarcoma [t(2;13) or t(1;13)]. The translocations result in novel proteins that are useful as diagnostic markers. The best-described translocation in leukemia is the Philadelphia chromosome’s t(9;22), which results in the BCR/ABL protein found in chronic myelogenous leukemia. This translocation results in a tyrosine kinase protein that is constitutively activated. In addition, the protein is localized to the cytoplasm instead of the nucleus, exposing the kinase to a new spectrum of substrates.

Alteration in the regulation of tumor-suppressor genes is another mechanism involved in oncogenesis. Tumor-suppressor genes are important regulators of cellular growth and apoptosis. They have been called recessive oncogenes because the inactivation of both alleles of a tumor-suppressor gene is required for expression of a malignant phenotype.

Knudson’s “2-hit” model of cancer development was based on the observation of the behavior of the RB tumor-suppressor gene. In sporadic cases of retinoblastoma, both alleles of the RB gene must be inactivated. However, in familial cases, children inherit an inactivated allele from 1 parent and consequently require the inactivation of the only remaining normal allele. This helps explain why familial cases of retinoblastoma occur earlier in childhood than sporadic cases, because only 1 “hit” is required.

Another major tumor-suppressor protein is P53, which is known as the “guardian of the genome” because it detects the presence of

ALL, acute lymphocytic leukemia; AML, acute myelocytic leukemia; APL, acute promyelocytic leukemia; CML, chronic myelogenous leukemia; MEN2, multiple endocrine neoplasia, type 2.
chromosomal damage and prevents the cell from dividing until repairs have been made. In the presence of damage beyond repair, P53 initiates apoptosis and the cell dies. More than 50% of all tumors have abnormal P53 proteins. Mutations in the P53 gene are important in many cancers, including breast, colorectal, lung, esophageal, stomach, ovarian, and prostate carcinomas as well as gliomas, sarcomas, and some leukemias.

PTEN (phosphatase and tensin homolog) is one of the most commonly lost tumor suppressors in human cancer. PTEN is a phosphatase that regulates cell-cycle progression. The dephosphorylation of proteins disrupts the Akt/PKB signaling pathway that moderates cell-cycle progression. Loss of PTEN enzyme activity is seen in Proteus, Cowden, and Bannayan-Riley-Ruvalcaba syndromes and in glioblastoma, endometrial carcinoma, and prostate cancer. Decreased phosphatase activity is found in lung and breast cancer. More than 170 putative tumor-suppressor genes are identified.

**SYNDROMES PREDISPOSING TO CANCER**
Several syndromes are associated with an increased risk of developing malignancies, which can be characterized by different mechanisms (Table 492-2). One mechanism involves the inactivation of tumor-suppressor genes such as RB in familial retinoblastoma. Interestingly, patients with retinoblastoma in which 1 of the alleles is inactivated throughout all of the patient's cells are also at a very high risk for developing osteosarcoma. A familial syndrome, Li-Fraumeni syndrome, in which 1 mutant P53 allele is inherited, also has been described in patients who develop sarcomas, leukemias, and cancers of the breast, bone, lung, and brain. Neurofibromatosis is a condition characterized by the proliferation of cells of neural crest origin, leading to neurofibromas. These patients are at a higher risk of developing malignant schwannomas and pheochromocytomas. Neurofibromatosis is often inherited in an autosomal dominant fashion, although 50% of the cases present without a family history and occur secondary to the high rate of spontaneous mutations of the NFI gene.

A second mechanism responsible for an inherited predisposition to develop cancer involves defects in DNA repair. Syndromes associated with an excessive number of broken chromosomes due to repair defects include Bloom syndrome (short stature, photosensitive telangiectatic erythema), ataxia-telangiectasia (childhood ataxia with progressive neurologic degeneration), and Fanconi anemia (short stature, skeletal and renal anomalies, pancytopenia). As a result of the decreased ability to repair chromosomal defects, cells accumulate abnormal DNA that results in significantly increased rates of cancer, especially leukemia. Xeroderma pigmentosum likewise increases the risk of skin cancer, owing to defects in repair to DNA damaged by ultraviolet light. These disorders display an autosomal recessive pattern.

ALL, acute lymphocytic leukemia; AML, acute myelocytic leukemia; GI, gastrointestinal; GU, genitourinary; JMML, juvenile myelomonocytic leukemia; NHPCC, nonhereditary polyposis colon cancer.
The third category of inherited cancer predisposition is characterized by defects in immune surveillance. This group includes patients with Wiskott-Aldrich syndrome, severe combined immunodeficiency, common variable immunodeficiency, and the X-linked lymphoproliferative syndrome. The most common types of malignancy in these patients are lymphoma and leukemia. Cure rates for immunodeficient children with cancer are much poorer than for nonimmunodeficient children with similar malignancies, suggesting a role for the immune system in cancer treatment as well as in cancer prevention.

**OTHER FACTORS ASSOCIATED WITH ONCOGENESIS**

**Viruses**

Several viruses have been implicated in the pathogenesis of malignancy. The association of the Epstein-Barr virus (EBV) with Burkitt lymphoma and nasopharyngeal carcinoma was identified more than 30 yr ago, but EBV infection alone is not sufficient for malignant transformation. EBV is also associated with mixed cellularity and lymphocyte-depleted Hodgkin disease, as well as some T-cell lymphomas, which is particularly intriguing because EBV normally does not infect T lymphocytes. The most conclusive evidence for a role of EBV in lymphogenesis is the direct causal role of EBV for B-cell lymphoproliferative disease in immunocompromised persons, especially those with AIDS.

Children who are chronically infected with hepatitis B (hepatitis B surface antigen–positive) have a ≥200-fold increased risk of developing hepatocellular carcinoma. In adults, the latency period between viral infection and the development of hepatocellular carcinoma approaches 20 yr. However, in children who acquire the viral infection through perinatal transmission, the latency period can be as short as 6–7 yr. The additional factors that are required for the malignant transformation of the virally infected hepatocytes are not clear. Hepatitis C virus infection is another risk factor for hepatocellular carcinoma and is also associated with splenic lymphoma.

Nearly all cervical carcinomas contain human papillomavirus (HPV). High-risk HPVs include types 16 and 18 but also types 31, 33, 35, 45, and 56, which are also commonly found in women without lesions. The low-risk HPVs, including 6 and 11 that are commonly found in genital warts, are almost never associated with malignancies. Like other virus-associated cancers, the presence of HPV alone is not sufficient to cause malignant transformation. The mechanism by which HPV 19 induces malignant transformation is thought to involve p53 and RB tumor-suppressor genes, which regulate the cell cycle by acting as gatekeepers of the G1/S and G2/M checkpoints. By interfering with these proteins, HPV alters the regulation of cell growth.

Human herpesvirus 8 is associated with Kaposi sarcoma, primary effusion B-cell lymphoma, and the plasma cell variant of Castleman disease, all of which occur primarily in persons with AIDS. Human T-cell leukemia virus 1 is associated with adult T-cell leukemia and lymphoma.

**Genomic Imprinting**

The development of cancer has also been linked to genomic imprinting, which is the selective inactivation of 1 of 2 alleles of a certain gene. The inactivated gene is determined by whether the gene is inherited from the mother or father. For example, normally the maternal IGF2 (insulin-like growth factor receptor 2) gene is inactivated. The inactivation is thought to be secondary to methylation of specific CpG sequences upstream of the IGF2 promoter, which interferes with the transcription of the IGF2 gene. In some Wilms tumors, there is loss of methylation in the upstream area of the maternal gene, which, in turn, allows transcript expression of the maternal IGF2 gene. At the same time the H19 gene (whose function is not yet clear), a previously actively transcribed maternal gene, is silenced by methylation. Beckwith-Wiedemann syndrome, an overgrowth syndrome characterized by macrosomia, macroglossia, hemihypertrophy, omphalocele, and renal anomalies, is associated with an increased risk of Wilms tumor, hepatoblastoma, rhabdomyosarcoma, neuroblastoma, and adrenal cortical carcinoma. The increased risk in developing cancer is associated with changes in the methylation pattern of genes on the 11p15 chromosome. Studies indicate that methylation patterns in a given individual change over time and that specific groups of methylation changes tend to cluster within families, suggesting heritability of the pattern of changes.

**Telomerase**

Telomeres are a series of tens to thousands of TTAGGG repeats at the ends of chromosomes that are important for stabilizing the chromosomal ends and limiting breakage, translocation, and loss of DNA material. With DNA replication there is a progressive shortening of telomere length, which is a hallmark of cellular aging and may be a senescence signal. In some instances telomerase, an enzyme that adds telomeres to the ends of chromosomes, becomes active. The addition of telomeres can be found in immortalized cell lines and most tumor types, and as a consequence, these cells might have a survival advantage, allowing them to undergo additional cell divisions. Therapy aimed at inhibiting telomerase activity can result in cell death.

*Bibliography is available at Expert Consult.*
Bibliography

Childhood cancer is uncommon and can manifest with symptoms seen with benign illnesses. The challenge for the pediatrician is to be alert to the clues suggesting a diagnosis of cancer. In addition to the classic manifestations, any persistent, unexplained symptom or sign should be evaluated as potentially emanating from a cancerous or precancerous condition. As part of the diagnostic evaluation, the pediatrician and pediatric oncologist must convey the possible diagnosis to the patient and family in a sensitive and informative manner.

**SIGNS AND SYMPTOMS**

The symptoms and signs of cancer are variable and nonspecific in pediatric patients. The types of cancer that occur during the 1st 20 yr of life vary dramatically as a function of age—more so than at any other comparable age range (see Chapter 491). Unlike cancers in adults, childhood cancers usually originate from the deeper, visceral structures and from the parenchyma of organs rather than from the epithelial layers that line the ducts and glands of organs and compose the skin. In children, dissemination of disease at diagnosis is common, and presenting symptoms or signs are often caused by systemic involvement. Pain was one of the initial presenting symptoms in more than 50% of children with cancer in one study. Infants and young children cannot express or localize their symptoms well. Another factor is the variability in the physiology and biology of the host that are related to growth and development during infancy, childhood, and adolescence.

The signs of cancer in children are often attributed to other causes before the malignancy is recognized. Delays in diagnosis are particularly problematic during late adolescence and are the result of a variety of factors prominent in this age group, including loss of health insurance coverage.

Although there is no clearly established set of warning signs of cancer in young people, the most common cancers in children suggest some guidelines that may be helpful in early recognition of signs and symptoms of cancer (Table 493-1). Most of the symptoms and signs are not specific and might represent other possibilities in a differential diagnosis. Nonetheless, these hints encompass the common cancers of childhood and have been very useful in early detection.

**PHYSICAL EXAMINATION**

Physical examination findings in a child with malignancy are dependent on whether the cancer is systemic (see Table 493-1) or localized. The cancers most common in children involve the lymphohematopoietic system. When the bone marrow is compromised by malignancy (e.g., leukemia, disseminated neuroblastoma), typical findings include pallor from anemia; bleeding, petechiae, or purpura from thrombocytopenia or coagulopathy; cellulitis or other localized infection from leukopenia; skin nodules (especially in infants) and hepatosplenomegaly from malignant leukocytosis. Abnormalities found in lymphatic malignancies include peripheral adenopathy (Fig. 493-1) and signs of superior vena cava syndrome from an anterior mediastinal mass (Fig. 493-2), including respiratory distress, and facial and neck plethora and edema. Enlargement of cervical lymph nodes is common in children, but when persistent, progressive, and painless it often suggests lymphoma. In particular, supraclavicular adenopathy suggests underlying malignancy.

Abnormalities of the central nervous system that can indicate cancer include decreased level of consciousness, cranial nerve palsies, ataxia, afebrile seizures, ptosis, decreased visual activity, neuroendocrine deficits, and increased intracranial pressure, which may be diagnosed by the presence of papilledema (Fig. 493-3). Any focal neurologic deficit in the motor or sensory system, especially a decrease in cranial nerve function, should prompt further investigation for malignancy.

Abdominal masses can be divided into upper, middle, and lower locations. Malignancies in the upper abdomen include Wilms tumor, neuroblastoma, hepatoblastoma, germ cell tumors, and sarcomas. Enlargement of the liver or spleen from leukemia can be mistaken for an upper abdominal mass. Midabdominal masses include non-Hodgkin lymphoma, neuroblastoma, germ cell tumors, and sarcomas. Lower abdominal masses include ovarian tumors, germ cell tumors, and sarcomas.

Rhabdomyosarcoma commonly appears as an extremity mass, particularly in adolescents. These tumors can be deceptively benign in appearance, but as with all unexplained masses they require immediate attention. Sacrococcygeal masses in neonates are usually teratomas, which are usually benign but can undergo malignant transformation if not removed promptly. Neuroblastoma can present as “blueberry muffin” spots on the skin of neonates or as periorbital ecchymosis in older children.

Ophthalmologic presentation of malignancy includes a white pupillary reflex (Fig. 493-4) rather than the usual red reflection from...

incident light. A white pupillary reflex is essentially pathognomonic for retinoblastoma, although some benign conditions can mimic this finding. Proptosis can be produced by rhabdomyosarcoma, neuroblastoma, lymphoma, and Langerhans cell histiocytosis. Horner syndrome, iris heterochromia, and opsoclonus-myoclonus all suggest a diagnosis of neuroblastoma.

**AGE-RELATED MANIFESTATIONS**

Because various types of cancer in children occur at specific ages, the physician should tailor the history and physical examination based on the age of the child. The embryonal tumors, including neuroblastoma, Wilms tumor, retinoblastoma, hepatoblastoma, and rhabdomyosarcoma, usually occur during the 1st 2 yr of life (see Fig. 491-4). From 1-4 yr of age, acute lymphoblastic leukemia peaks in incidence. Brain tumors have a peak incidence in the 1st decade of life. Non-Hodgkin lymphomas are uncommon earlier than 5 yr of age but steadily increase thereafter. During adolescence, bone tumors, Hodgkin disease, and the gonadal and soft tissue sarcomas predominate. Hence, for infants and toddlers, special attention should be paid to the possibility of embryonal and intraabdominal tumors. Preschool-age and early school-age children showing compatible signs and symptoms should be specifically evaluated for leukemia. School-age children might present with lymphoma or with brain tumors. Adolescents require assessment for bone and soft tissue sarcomas and gonadal malignancies, as well as for Hodgkin lymphoma.

**EARLY DETECTION**

The prognosis of malignancy in children depends primarily on tumor type, extent of disease at diagnosis, and rapidity of response to treatment. Early diagnosis helps to ensure that appropriate therapy is given in a timely fashion and hence optimizes the chances of cure. Because most physicians in general practice rarely encounter children with undiagnosed cancer, they should remember to investigate the possibility of malignancy, especially when they encounter an atypical course of a common childhood condition, unusual manifestations that do not fit common conditions, and any persistent symptom that defies diagnosis.

Delays in diagnosis are particularly likely in certain clinical situations. The cardinal symptom of both osteosarcoma and Ewing sarcoma is localized and usually persistent pain. Because these tumors occur during the 2nd decade of life, a time of increased physical activity, patients often assume the pain results from trauma. Prompt radiologic evaluation can help confirm the diagnosis. Lymphoma, especially during adolescence, often manifests as an anterior mediastinal mass. Symptoms such as chronic cough, unexplained shortness of breath, or “new-onset asthma” are typical with this presentation and are often overlooked. Tumors of the nasopharynx or middle ear can mimic infection. Prolonged, unexplained ear pain, nasal discharge, retropharyngeal swelling, and trismus should be investigated as possible signs of malignancy.

Early symptoms of leukemia may be limited to prolonged or unexplained low-grade fever or bone and joint pain. Blood counts with abnormalities in two or more cell lines might indicate the need for bone marrow examination, even when leukemic blast cells are not seen in the blood smear (see Table 493-1).

Mass screening for children with malignancy is not feasible. A screening program to detect early-stage neuroblastoma was successful in documenting more cases of the disease, but it had no impact on overall outcome. However, certain children are at increased risk for cancer and require an individualized plan to ensure early detection of malignancy. Selected examples include children with certain chromosome abnormalities, such as Down syndrome, Klinefelter syndrome, WAGR syndrome (Wilms tumor, aniridia, genital abnormalities, and mental retardation); children with overgrowth syndromes, such as Beckwith-Wiedemann syndrome, and hemihypertrophy; children with certain inherited single-gene disorders, including retinoblastoma, P53 mutations (Li-Fraumeni syndrome), familial adenomatous polyposis, and neurofibromatosis (see Table 492-2).

**ENSURING THE DIAGNOSIS**

When a malignant neoplasm is suspected, the immediate goal is to confirm the diagnosis. A tentative diagnosis can often be established on the basis of the patient’s age, symptoms, and location of masses. Selected imaging techniques and tumor markers can facilitate the diagnostic approach (Table 493-2). Especially when a solid tumor is present,

AFP, α-Fetoprotein; CNS, central nervous system; CSF, cerebrospinal fluid; HCG, human chorionic gonadotropin; HVA, homovanillic acid; MIBG, metaiodobenzylguanidine; PET, positron emission tomography; VMA, vanillylmandelic acid.

the pediatric oncologist, surgeon, and pathologist should work as a team to determine the site of biopsy, amount of tissue required, and whether fine-needle aspiration, percutaneous image-guided biopsy, incisional biopsy, or excisional biopsy and tumor resection are indicated. For selected situations, at the time of the initial diagnostic procedure, plans for bone marrow aspiration and biopsy and placement of central venous access may be appropriate.

Pathologic evaluation of pediatric malignancies requires appropriate handling of tissue so that multiple different techniques can be used. It is important that fresh tissue not be placed in formalin. Besides routine light microscopy, pathologic evaluation may include immunohistochemistry, flow cytometry, cytogenetics, and molecular genetic studies (fluorescence in situ hybridization, reverse-transcriptase polymerase chain reaction). Emerging technologies include DNA microarray analysis and cancer genome sequencing that can identify specific gene expression patterns and sequences in tumors. In time, these technologies might ensure more accurate classification and treatment.

STAGING

Once a specific diagnosis is confirmed, studies to define the extent of the malignancy are necessary to determine prognosis and treatment. Table 493-2 outlines the minimum evaluation required for common pediatric malignancies. In addition, for many tumors (e.g., Wilms tumor, neuroblastoma, rhabdomyosarcoma) a surgical staging system is used. Surgical stage can be determined at the time of the initial diagnostic procedure or subsequently. For example, a patient who has abdominal surgery for possible Wilms tumor or neuroblastoma should have careful evaluation and biopsy of all adjacent lymph nodes. A child with rhabdomyosarcoma can require a subsequent biopsy of sentinel lymph nodes as determined by scintigraphy or dye injection adjacent to the primary tumor. The pathologist facilitates staging by examining margins of the specimen to determine residual tumor.

Chapter 494

Principles of Treatment

Archie Bleyer, A. Kim Ritchey, and Erika Friehling

Treatment of children with cancer begins with an absolute requirement for the correct diagnosis (including subtype), proceeds through accurate and thorough staging of the extent of disease and determination of prognostic subgroup, provides appropriate multidisciplinary and usually multimodal therapy, and requires assiduous evaluation of the possibilities of recurrent disease and of adverse late effects of the disease and the therapies rendered. Throughout treatment, every child with cancer should have the benefit of the expertise of specialized teams of providers of pediatric cancer care, including pediatric oncologists, pathologists, radiologists, surgeons, radiotherapists, nurses, and support staff, including nutritionists, social workers, psychologists, pharmacists, other medical specialists, and teachers trained to work with seriously ill children.

The best chance for cure of cancer is during the initial course of treatment; the cure rates for patients with recurrent disease are much lower than those for patients with primary disease. All patients with cancer should be referred to an appropriate specialized center as soon as possible when the diagnosis of cancer is suspected. All such centers in North America are identified on the Children’s Oncology Group website (http://www.childrensoncologygroup.org) and on the National Cancer Institute cancer trials website (http://www.clinicaltrials.gov). The remarkable increases in cure rates for childhood malignancies since the 1970s would not have occurred without the collective participation of patients and their physicians in clinical research programs at these centers. In the United States, the National Cancer Institute’s Clinical Trials Cooperative Groups Program is associated with a >80% reduction in the incidence of mortality from childhood cancer despite an overall increase in cancer incidence during this interval (Fig. 494-1). After what appeared to be a plateau in the rate of decline in mortality in the early 2000s, there is now evidence that the mortality rate
**Principles**

A favorable prognosis is a definite risk if the patient is not referred to appropriate treatment, or elimination of at least one treatment modality continues to decline. Notably, a greater decline in mortality has been seen in the adolescent and young adult population when compared to younger children (15 yr old, reversing prior trends (Fig. 494-2). The most current information on treatment of all types of childhood cancer is available in the PDQ [Physician Data Query] on the National Cancer Institute website (http://www.cancer.gov/cancertopics/pdq/pediatrictreatment/).

**DIAGNOSIS AND STAGING**

Accurate diagnosis and staging of the extent of disease are imperative, especially for childhood cancers that have high cure rates, because the nature of therapy depends strongly on the type of cancer. In addition, **prognostic subgroups** based on the stage of disease have been established for most cancers that occur in children. Accordingly, children with a better prognosis are treated with less-intensive therapy, including lower doses of chemotherapy or radiation therapy, a shorter duration of treatment, or elimination of at least one treatment modality (radiation therapy, chemotherapy, surgery). Accurate staging thus reduces the risk of excessive acute adverse effects and long-term complications of therapy in patients whose prognosis indicates that less therapy is required for cure. Overtreatment of patients with a more favorable prognosis is a definite risk if the patient is not referred to a cancer treatment center for management of adverse effects of such treatment. Conversely, undertreatment also is a clear risk if the diagnosis and stage are not correct, resulting in a compromise of an otherwise high potential for cure.

**Diagnostic imaging** is a critical phase of evaluation in most children with solid tumors (i.e., cancers other than leukemia). MRI, CT, ultrasonography, scintigraphy (nuclear medicine scans), positron emission tomography, and spectroscopy, as appropriate, all serve a clear purpose in the evaluation of children with cancer, not only before treatment to determine the extent of disease and the appropriate therapy but also during follow-up to determine whether the therapy was effective. In addition, response to treatment as determined by imaging techniques is being increasingly used to guide changes in the therapy.

Expertise in pathology and laboratory medicine provides critical diagnostic support and guides therapy in most children with cancer. Relatively noninvasive methods of obtaining tumor tissue (such as fine-needle aspiration and percutaneous image-guided biopsies) can be performed in pediatric centers with appropriate expertise in diagnostic imaging, interventional radiology, cytology, and anesthesia support. Sentinel node mapping is increasingly being applied in the staging of children’s cancers. Determining the adequacy of surgery by evaluating frozen sections of the surgical margins for tumor cells is essential in many tumor operations.

**A MULTIMODAL, MULTIDISCIPLINARY APPROACH**

Many pediatric subspecialties are involved in the evaluation, treatment, and management of children with cancer, including provision of primary therapy and supportive care services (Fig. 494-3). More than two of the primary modalities are often used together, with chemotherapy being the most widely used, followed, in order of use, by surgery, radiation therapy, and biologic agent therapy (Fig. 494-4).

The leukemias that occur in childhood usually are managed with chemotherapy alone, with a small proportion of patients receiving cranial or craniospinal radiation therapy to prevent or treat overt central nervous system (CNS) leukemia. Children with non-Hodgkin

**Figure 494-2** Age-adjusted mortality trends for all malignant cancers among children age <20 years in the United States from 1975 through 2010 along with annual percentage changes (APCs) for joinpoint segments. Asterisk indicates that the slope of the joinpoint segment is statistically different from zero (<0.05). The green line indicates leukemias and lymphomas, and the blue line indicates all other cancer sites. CI indicates confidence interval. (From Smith MA, Altekruse SF, Adamson PC, et al: Declining childhood and adolescent cancer mortality, Cancer 120:2497-2506, 2014.)

**Chapter 494  •  Principles of Treatment  •  2427**
lymphoma also are treated with chemotherapy alone, with the exception of radiation therapy for CNS involvement. Localized therapy with surgery or irradiation, or both, is an important component of treatment of most solid tumors, including Hodgkin lymphoma, but systemic multiagent chemotherapy usually is necessary because tumor dissemination generally is present even if it is undetectable. Chemotherapy alone usually is not adequate to eradicate gross residual tumors. Hence, it is not unusual for children with malignant tumors to require treatment with all 3 modalities (see Fig. 494-3). Unfortunately, most treatments that are effective in children with cancer have a narrow therapeutic index (a low ratio of efficacy to toxicity). The acute and chronic adverse effects of these treatments can be minimized but not entirely avoided.

Biologic agent therapy has become an important modality in a few childhood cancers (see Fig. 494-4). This type of treatment generally refers to immunotherapy, biologic response modifiers, or endogenously occurring molecules that have therapeutic effects in supraphysiologic doses. Examples are retinoic acid therapy in acute promyelocytic leukemia, monoclonal antibody therapy for neuroblastoma and certain non-Hodgkin lymphomas, tyrosine kinase inhibitors such as imatinib mesylate for chronic myelogenous and Philadelphia chromosome-positive leukemias, and radioactive metaiodobenzylguanidine therapy for neuroblastoma.

Chemotherapy is used more widely in children than in adults because children better tolerate the acute adverse effects and the malignant diseases that occur in childhood are more responsive to chemotherapy than are malignant diseases of adults. Radiation therapy is used sparingly in children because they are more vulnerable than adults to its late adverse effects.

Whenever possible, treatment is given on an outpatient basis. Children should remain living at home and in school as much as possible throughout treatment. Increasingly, pediatric cancer therapies are being administered to ambulatory patients, with the advent of such innovations as programmable infusion pumps, oral chemotherapeutic regimens, early discharge from hospital with intensive outpatient supportive care, and home healthcare services. Some patients miss a considerable amount of school in the 1st yr after diagnosis because of the intensity of therapy or its adverse effects and of the ensuing complications of the disease or therapy. Tutoring should be encouraged so that children do not fall behind in their schooling; counseling should be provided as appropriate. In-hospital school services should be provided for patients who must spend much of their time as inpatients receiving therapy for disease or for managing adverse effects.

Development of selective, highly effective therapy for cancer in both children and adults had been hindered by a lack of understanding of the molecular mechanisms that underlie malignant transformation. De novo or acquired resistance to chemotherapy and radiation therapy remains an obstacle to cure. Ongoing discoveries of molecular and cellular mechanisms that explain the cancer process have led to increasingly specific antineoplastic therapies, generally referred to as molecule-targeted therapies. Their most prominent feature is a relative lack of normal tissue toxicity, such that the additional therapeutic benefit occurs with minimum additional toxicity. Many of the new biologic agent therapies, such as imatinib and rituximab, fall into this category (Table 494-1). Complementary and alternative remedies are increasingly being provided by parents to their children with cancer, with or without knowledge of the medical professionals entrusted with the child’s care (see Chapter 64). Many of these have not been evaluated by rigorous testing and most are ineffective; some are toxic or interfere with the metabolism of other drugs.

**DISCUSSING THE TREATMENT PLAN WITH THE PATIENT AND FAMILY**

The diagnostic and treatment plan must be carefully explained to parents and, if the child is old enough to understand, to the patient. An honest discussion of the facts is the best policy. Children should be given as much information as they can understand and would find useful or that information they express a desire or wish to know. Effects of treatment, such as the possible need to amputate a limb, loss of hair during chemotherapy, and possible temporary or permanent functional impairment must be anticipated and fully discussed. The possibility and probability of death from cancer should be covered in an age-appropriate manner. It usually is necessary to repeat explanations several times before distraught family members fully understand. Throughout treatment, parents, patients, siblings, and medical staff will need help in expressing feelings of anxiety, depression, guilt, and anger. The pediatrician, pediatric oncologist, and nurses should call on experienced professionals, including pediatric social workers, child

Comments

Methotrexate
Folic acid antagonist; inhibits dihydrofolate reductase
ALL, non-Hodgkin lymphoma, osteosarcoma, Hodgkin lymphoma, medulloblastoma
Myelosuppression, mucositis, stomatitis, dermatitis, hepatitis
With long-term administration; osteopenia and bone fractures
With high-dose administration; renal and CNS toxicity
With intrathecal administration; arachnoiditis, leukoencephalopathy, leukomyelopathy
Systemic administration may be PO, IM, or IV; also may be administered intrathecally
Plasma methotrexate levels must be monitored with high-dose therapy and when low doses are administered to patients with renal dysfunction, and leucovorin rescue applied accordingly
Allopurinol inhibits metabolism

6-Mercaptopurine (Purinethol)

Cytarabine (cytosine arabinoside; Ara-C)
Pyrimidine analog; inhibits DNA polymerase
ALL, AML, non-Hodgkin lymphoma, Hodgkin lymphoma
Nausea, vomiting, myelosuppression, conjunctivitis, mucositis, CNS dysfunction
With intrathecal administration; arachnoiditis, leukoencephalopathy, leukomyelopathy
Systemic administration may be PO, IM, or IV; may also be administered intrathecally

Cyclophosphamide (Cytoxan)

Ifosfamide (Ifex)

Requires hepatic activation and thus is less effective in presence of liver dysfunction.
Mesna prevents hemorrhagic cystitis

TREATMENTS
Chemotherapy
The most widely used modality in pediatric cancer therapy is chemotherapy (see Fig. 494-3). Therapy nearly always involves combinations of drugs, such as VAC (vincristine, dactinomycin [Actinomycin D], and cyclophosphamide) and CHOP (cyclophosphamide, doxorubicin [hydroydaunorubicin/Adriamycin], vincristine [Oncovin], and prednisone). Sequential single-drug therapy rarely results in complete responses, and partial responses usually are infrequent and transient and grow progressively shorter in duration with each drug used. Combination chemotherapy is the standard when combinations of drugs with different mechanisms of action and non-overlapping toxicities were first demonstrated to be effective in childhood leukemia. Most of the cytotoxic drugs for childhood cancer are selected from several classes of agents, including alkylating agents, antimetabolites, antibiotics, hormones, plant alkaloids, and topoisomerase inhibitors (Table 494-2). The increased metabolic and cell-cycle activity of malignant cells makes them more susceptible to the cytotoxic effects of these types of agents (Fig. 494-5).

Because most antineoplastic agents are cell-cycle dependent, their adverse effects usually are related to the proliferation kinetics of individual cell populations. Most susceptible are tissues or organs with high rates of cell turnover: bone marrow, oral and intestinal mucosa, epithelial cell populations. Most susceptible are tissues or organs with high rates of cell turnover: bone marrow, oral and intestinal mucosa, epidermis, liver, and spermatagonia. The most common acute adverse

effects are myelosuppression (with neutropenia and thrombocytopenia being the most problematic), immunosuppression, nausea and vomiting, hepatic dysfunction, upper and lower gastrointestinal mucositis, dermatitis, and alopecia. Fortunately, the tissues affected also recover relatively quickly, so that the acute adverse effects are nearly always reversible. Life-threatening effects of many chemotherapy agents include severe neutropenia with infection, fungemia or fungal pneumonia as a result of immunosuppression, and septicemia, not infrequently linked to indwelling intravascular devices (Table 494-3; see Chapters 178 and 179). Cardiomyopathy caused by anthracyclines (e.g., doxorubicin and daunorubicin) and renal failure from platinum-containing agents also may be life-threatening or disabling.

Least susceptible to chemotherapy and radiation therapy are cells that do not replicate or that replicate slowly, such as neurons, muscle cells, connective tissue, and bone. However, children are not exempt from toxicities of these tissues, probably because they are still undergoing proliferation, albeit at a slower pace than other tissues, during growth and growth spurts.

Physically, children can endure the acute adverse effects of chemotherapy better than adults can in many ways. The maximum tolerated dosage in children, when expressed on the basis of body surface area or body weight, commonly is greater than that in adults. A comparison of anticancer drugs tested in phase I trials in both adult and pediatric patients showed that the maximum tolerated dosage in children was greater than that in adults for 70% of the agents, equal to that in adults for 15% of the agents, and less than the adult dose for only 15% of the agents. For all the drugs that were compared, the mean pediatric maximum tolerated dosage was greater than the adult mean.

Tumor-directed therapies are evolving in the field of pediatric oncology. Tumor antigen–specific monoclonal antibodies have been incorporated into the standard therapy of neuroblastoma (anti–ganglioside GD). The antiangiogenic agent bevacizumab (monoclonal antibody against vascular endothelial growth factor A) shows promise in the treatment of CNS tumors, especially low-grade gliomas.

**Surgery**

Superb pediatric surgical and anesthesia services are indispensable for children with cancer. The pediatric surgeon’s role varies, depending on the type of tumor. For solid tumors, complete resection with...
documented evidence of negative margins often is required for cure or long-term control. Considerable prolongation of life nearly always depends on whether the tumor is resectable and on the actual extent of resection.

With the exception of brainstem tumors and retinoblastoma, all solid tumors in children require a tissue diagnosis; therefore, biopsy of the suspected neoplasm is paramount. Staging with sentinel node biopsies has become the standard of care for several pediatric malignancies. Surgical expertise is essential for implantation of vascular access devices and removal and replacement of such devices when infection or thrombosis supervenes (see Chapter 179).

Increasingly, minimally invasive endoscopic surgical techniques are being used when indicated and, if the patient's condition permits, for biopsy and resection of tumor, direct ascertainment of residual disease and assessment of response, lysis of adhesions, and splenectomy.

**Radiation Therapy**

Radiation therapy is used sparingly in children, who are more susceptible than are adults to the adverse delayed effects of ionizing radiation. A major advance in pediatric radiation therapy is the application of conformal irradiation to children with cancer. This technique, most commonly applied as intensity-modulated radiation therapy, spares normal tissue by conforming the radiation volume to the shape of the tumor, thereby enabling delivery of higher doses to the tumor with lower exposure of normal tissue adjacent to the tumor or in the path of the radiation beam. Another example is proton-beam radiotherapy, which has just begun to be more widely available for children with cancer. With more focused beams and better sedation and immobilization techniques, radiation therapy is becoming more commonly used in children. Acute adverse effects from radiation therapy are less severe than those from chemotherapy and depend on which part of the body is irradiated and the means of administration. Dermatitis is the most common general adverse effect, because skin is always in the treatment field. Nausea and diarrhea are common subacute adverse effects with abdominal radiation therapy. Mucositis nearly always occurs to some extent whenever oral or intestinal mucosa is in the treatment volume. Somnolence is common with cranial irradiation. Alopecia occurs where hair is in the radiation field.

Most radiation therapy schedules require treatment 5 days per week for 4–7 wk, depending on the dose needed to control the tumor and on the amount and nature of normal tissue in the field. Most adverse effects are not noted until the second half of the course of irradiation. Late effects can occur months to years after radiation therapy and usually are dose-limiting manifestations. The type of delayed toxicity also depends on the site of irradiation. Examples are impaired growth resulting from cranial or vertebral irradiation, endocrine dysfunction from midbrain irradiation, pulmonary or cardiac insufficiency from chest irradiation, strictures and adhesions from abdominal irradiation, and infertility from pelvic irradiation. Second malignancy can also develop in the radiation field, for example, breast cancer from chest irradiation and brain tumors from CNS irradiation.

**ACUTE TOXIC EFFECTS AND SUPPORTIVE CARE**

Adverse treatment effects that occur early in therapy can result in oncologic emergencies. These include metabolic disorders, bone marrow suppression, and compression by tumors on vital structures (Table 494-4). In tumor lysis syndrome (TLS), uric acid, phosphates, and potassium are released in the circulation in large quantities from death of tumor cells. Hyperuricemia can lead to impairment of renal function, which further exacerbates the metabolic abnormalities. TLS can occur before therapy in patients with a large tumor burden (e.g., Burkitt lymphoma, lymphoblastic lymphoma, and high white blood cell count leukemia), but it is usually seen within 12–48 h of initiating chemotherapy. TLS is infrequently reported in other tumors (Hodgkin lymphoma, neuroblastoma, hepatoblastoma). Before therapy is initiated, the serum levels of uric acid, electrolytes, calcium, phosphorus, and creatinine should be measured and adequate hydration ensured. Allopurinol (a xanthine oxidase inhibitor) should be started to prevent further accumulation of uric acid. In patients with established TLS with high uric acid levels or those at high risk for TLS, rasburicase (an enzyme that degrades uric acid) should be given instead of allopurinol. Symptomatic hypokalemia and hyperphosphatemia with subsequent hypocalcemia can develop in the setting of inadequate renal function.

Virtually all chemotherapy regimens can produce myelosuppression, as can malignancies that invade and replace bone marrow. Anemia can be corrected by transfusions of packed erythrocytes, and thrombocytopenia can be corrected by platelet infusions. Patients receiving immunosuppressive therapy should receive irradiated blood products to prevent graft-versus-host disease and leukoreduced blood products to prevent transfusion-associated reactions and infections. Neutropenia (neutrophil counts <500/µL) poses a risk of life-threatening infection. Febrile neutropenic patients should be hospitalized and treated with empiric broad-spectrum intravenous antimicrobial therapy pending the results of appropriate cultures of blood, urine, or any obvious sites of infection (see Chapter 178). Treatment is continued until fever resolves and the neutrophil count rises. If fever persists for more than 3–5 days while the patient is receiving broad-spectrum antibiotics, the possibility of fungal infection must be considered. Fungal infections caused by Candida and Aspergillus are common in immunosuppressed patients. Opportunistic organisms such as Pneumocystis jiroveci can produce fatal pneumonia. Prophylactic treatment with trimethoprim-sulfamethoxazole is given when severe or prolonged immunosuppression is anticipated.

Viruses of low pathogenicity can produce serious disease in the setting of immunosuppression caused by malignancy or its treatment. Patients should not be given live virus vaccines. Children who are receiving chemotherapy and who are exposed to chickenpox should receive varicella-zoster immunoglobulin, or, if varicella-zoster immunoglobulin is not available, oral acyclovir should be considered. If clinical disease develops, the child should be hospitalized and treated with intravenous acyclovir.

Adequate pain management is critical. The World Health Organization (WHO) guidelines are particularly useful in the management of pain associated with cancer and cancer therapy (see Chapter 62). Depending on the type of cancer therapy, patients can lose more than 10% of body weight. Patients sometimes reduce their food intake because of temporary, treatment-associated nausea, stomatitis, and vomiting. Appetite loss is not a cause for alarm. Malnutrition is a particular risk in patients receiving radiation therapy involving the abdomen or the head and neck, intensive chemotherapy, or total-body irradiation and high-dose chemotherapy before marrow transplantation. If oral supplementation proves inadequate, such patients can require enteral tube feedings or parenteral hyperalimentation.

**LATE ADVERSE EFFECTS**

Injury to tissues with low repair potential often results in long-lasting or permanent deficit. These effects can be either from the tumor or its treatment. For example, a brain or spinal tumor can leave the child with a permanent paresis or autonomic dysfunction, anthracycline-induced cardiomyopathy usually produces refractory cardiac dysfunction, and the leukoencephalopathy caused by intrathecal methotrexate and by CNS radiation therapy often is only partially reversible. The potential types of late adverse effects depend on the child's age at the time of treatment, the location(s) of the cancer, and the therapy administered. A good resource for the pediatrician, patient, and family who have to anticipate the possibilities is available at http://www.survivorshipguidelines.org.

Late adverse effects of therapy can cause substantial morbidity (Table 494-5). Successful surgical resection can result in loss of important functional structures. Irradiation can produce irreversible organ damage, with symptoms and functional limitations depending on the organ involved and the severity of the damage. Many problems related to radiation therapy do not become obvious until the patient is fully grown, such as asymmetry between irradiated and nonirradiated areas or extremities. Irradiation of fields that include endocrine organs can cause hypothyroidism, pituitary dysfunction, or infertility. In sufficient

- Sarcoma (chest wall or intrathoracic)

- Autologous or allogeneic HSCT

**GASTROINTESTINAL**

- Chronic enterocolitis

- Strictures

- Bowel obstruction

- Radiation affecting gastrointestinal tract (≥30 Gy)

- Abdominal surgery

- Higher radiation dose to bowel (≥45 Gy)

- Combined modality therapy with abdominal irradiation and radiomimetic chemotherapy (dactinomycin or anthracyclines)

- Combined modality therapy with abdominal surgery and irradiation

- Sarcoma (retroperitoneal or pelvic primary)

**HEPATIC**

- Hepatic fibrosis

- Cirrhosis

- Radiation affecting liver

- Higher radiation dose or treatment volume (20-30 Gy to entire liver or ≥40 Gy to at least one third of liver)

- Sarcoma

- Neuroblastoma

**RENAL**

- Renal insufficiency

- Hypertension

- Glomerular injury

- Tubular injury

- Chemotherapy: Ifosfamide, Cisplatin, Carboplatin

- Radiation affecting kidneys:
  - Whole abdomen
  - Upper abdominal fields
  - TBI

GH, Growth hormone; HPA, hypothalamic–pituitary–adrenal axis; HSCT, hematopoietic stem cell transplantation; TBI, total-body irradiation.

Group 1. Low risk of late effects:
- Surgery only
- Chemotherapy did not include alkylating agent, anthracycline, bleomycin, or epipodophyllotoxin
- No radiation

Group 2. Moderate risk:
- Low or moderate dose alkylating agent, anthracycline, bleomycin, or epipodophyllotoxin
- No radiation

Group 3. High risk:
- Any radiation
- High dose alkylating agent, anthracycline, bleomycin, or epipodophyllotoxin
- Stem cell transplant

Communication points with primary care physician

b. Cancer summary: cancer diagnosis, cancer therapy, surveillance recommendations, contact information
c. Periodic update with changes in surveillance recommendations and new information regarding potential late effects
d. Periodic update of survivor’s health for primary care physician’s record

Figure 494-6 Proposed risk-stratified shared care model for childhood cancer survivors. Solid line denotes primary responsibility for risk-based care; risk stratification based upon determination of the long-term follow-up staff. CA, Cancer; DX, diagnosis; Onc, oncologist; PCP, primary care provider; RX, therapy. (Adapted from Oeffinger KC, McCabe MS. Models for delivering survivorship care, J Clin Oncol 24(32):5119, 2006; with permission from the American Society of Clinical Oncology. From Oeffinger KC, Nathan PC, Kremer LCM: Challenges after curative treatment for childhood cancer and long-term follow up of survivors, Pediatr Clin North Am 55:251–273, 2008.)

doses, cranial irradiation can produce neurologic dysfunction and spinal irradiation can produce growth retardation.

Chemotherapy also carries the risk of long-lasting organ damage. Of particular concern are leukoencephalopathy after high-dose methotrexate therapy; infertility in male patients treated with alkylating agents (e.g., cyclophosphamide); myocardial damage caused by anthracyclines; pulmonary fibrosis caused by bleomycin; renal dysfunction caused by ifosfamide, nitrosourea, or platinum agents; and hearing loss from cisplatin. Development of these sequelae may be dose-related and usually is irreversible. Appropriate baseline and intermittent testing should be performed before these drugs are administered to ensure that there is no preexisting damage to the organs likely to be affected and to permit monitoring of the adverse effects of treatment-induced changes.

Perhaps the most serious late adverse effect is the occurrence of second cancers in patients successfully cured of a first malignancy. The risk appears to be cumulative, increasing by approximately 0.5% per year, resulting in approximately a 12% incidence at 25 yr after treatment. Patients who have been treated for childhood cancer should be examined annually, with particular attention to possible late adverse effects of therapy, including second malignancies (Fig. 494-6).

PALLIATIVE CARE
At all stages of caring for children with cancer, principles of palliative care should be applied to relieve pain and suffering and to provide comfort (see Chapter 43). Pain is a serious cause of suffering among patients with cancer. It may be the result of organ obstruction or compression or bone metastasis, or it may be neuropathic. Pain should be managed in a stepwise manner, as recommended by the WHO, in accordance with the principles of selecting the appropriate analgesic, prescribing the appropriate dosage, administering the drug by the appropriate route, and choosing an appropriate dosing schedule to prevent persistent pain and to relieve breakthrough pain (see Chapter 62). In addition, the dosage should be titrated aggressively while attempts are made to prevent, anticipate, and manage side effects. Adjuvant drugs and sequential trials of analgesic drugs should be considered.

The goals in the care of dying patients are to avoid distress for the patient, family, and caregivers; to provide care consistent with the patient’s and family’s wishes; and to comply with and advocate for clinical, cultural, and ethical standards.

Bibliography is available at Expert Consult.
The leukemias are the most common malignant neoplasms in childhood, accounting for approximately 31% of all malignancies that occur in children younger than 15 yr of age. Each year leukemia is diagnosed in approximately 3,250 children younger than 15 yr of age in the United States, an annual incidence of 4.5 cases per 100,000 children. Acute lymphoblastic leukemia (ALL) accounts for approximately 77% of cases of childhood leukemia, acute myelogenous leukemia (AML) for approximately 11%, chronic myelogenous leukemia (CML) for 2-3%, and juvenile myelomonocytic leukemia (JMML) for 1-2%. The remaining cases consist of a variety of acute and chronic leukemias that do not fit classic definitions for ALL, AML, CML, or JMML.

The leukemias may be defined as a group of malignant diseases in which genetic abnormalities in a hematopoietic cell give rise to an unregulated clonal proliferation of cells. The progeny of these cells have a growth advantage over normal cellular elements, because of their increased rate of proliferation and a decreased rate of spontaneous apoptosis. The result is a disruption of normal marrow function and, ultimately, marrow failure. The clinical features, laboratory findings, and responses to therapy vary depending on the type of leukemia.

495.1 Acute Lymphoblastic Leukemia

Erika Friehling, A. Kim Ritchey, David G. Tubergen, and Archie Bleyer

Childhood ALL was the first disseminated cancer shown to be curable. It actually is a heterogeneous group of malignancies with a number of distinctive genetic abnormalities that result in varying clinical behaviors and responses to therapy.

EPIDEMIOLOGY

ALL is diagnosed in approximately 2,400 children younger than 15 yr of age in the United States each year. ALL has a striking peak incidence at 2-3 yr of age and occurs more in boys than in girls at all ages. This peak age incidence was apparent decades ago in white populations in advanced socioeconomic countries, but it has since been confirmed in the black population of the United States as well. The disease is more common in children with certain chromosomal abnormalities, such as Down syndrome, Bloom syndrome, ataxia-telangiectasia, and Fanconi anemia. Among identical twins, the risk to the second twin if 1 twin develops leukemia is greater than that in the general population. The risk is >70% if ALL is diagnosed in the first twin during the 1st yr of life and the twins shared the same (monochorionic) placenta. If the first twin develops ALL by 5-7 yr of age, the risk to the second twin is at least twice that of the general population, regardless of zygosity.

ETIOLOGY

In virtually all cases, the etiology of ALL is unknown, although several genetic and environmental factors are associated with childhood leukemia (Table 495-1). Most cases of ALL are thought to be caused by postconception somatic mutations in lymphoid cells. However, the identification of the leukemia-specific fusion-gene sequences in archived neonatal blood spots of some children who develop ALL at a later date indicates the importance of in utero events in the initiation of the malignant process in some cases. The long lag period before the onset of the disease in some children, reported to be as long as 14 yr, supports the concept that additional genetic modifications are required for disease expression. Moreover, those same mutations have been found in neonatal blood spots of children who never go on to develop leukemia.

Exposure to medical diagnostic radiation both in utero and in childhood is associated with an increased incidence of ALL. In addition, published descriptions and investigations of geographic clusters of cases have raised concern that environmental factors can increase the incidence of ALL. Thus far, no such factors other than radiation have been identified in the United States. In certain developing countries, there is an association between B-cell ALL (B-ALL) and Epstein-Barr viral infections.

CELLULAR CLASSIFICATION

The classification of ALL depends on characterizing the malignant cells in the bone marrow to determine the morphology, phenotype as measured by cell membrane markers, and cytogenetic and molecular genetic features. **Morphology** is usually adequate alone to establish a diagnosis, but the other studies are essential for disease classification, which can have a major influence on the prognosis and the choice of appropriate therapy. The current system used is the World Health Organization (WHO) classification of leukemias. Phenotypically, surface markers show that approximately 85% of cases of ALL are classified as B lymphoblastic leukemia (previously termed precursor B-ALL or pre-B-ALL), approximately 15% are T-lymphoblastic leukemia, and approximately 1% are derived from mature B cells. The rare leukemia of mature B cells is termed Burkitt leukemia and is one of the most rapidly growing cancers in humans, requiring a different therapeutic approach than other subtypes of ALL. A small percentage of children with leukemia have a disease characterized by surface markers of both lymphoid and myeloid derivation.

Chromosomal abnormalities are used to subclassify ALL into prognostic groups (Table 495-2). Many genetic alterations, including inactivation of tumor-suppressor genes and mutations that activate the **NOTCH1** or **RAS** pathways, have been discovered and might one day be incorporated into clinical practice (Fig. 495-1).

The polymerase chain reaction and fluorescence in situ hybridization techniques offer the ability to pinpoint molecular genetic abnormalities and can be used to detect small numbers of malignant cells at diagnosis as well as during follow-up (minimal residual disease [MRD], see below) and are of proven clinical utility. The development of DNA microanalysis makes it possible to analyze the expression of thousands of genes in the leukemic cell. This technique promises to further enhance the understanding of the fundamental biology and to provide clues to the therapeutic approach of ALL.

CLINICAL MANIFESTATIONS

The initial presentation of ALL usually is nonspecific and relatively brief. Anorexia, fatigue, malaise, and irritability often are present, as is

Figure 495-1 Estimated frequency of specific genotypes in childhood ALL. The genetic lesions that are exclusively seen in cases of T-cell ALL are indicated in gold and those commonly associated with B-cell ALL in blue. The darker gold or blue color indicates those subtypes generally associated with poor prognosis. (From Pui CH, Mullighan CG, Evans WE. Pediatric acute lymphoblastic leukemia: where are we going and how do we get there? Blood 120:1165–1174, 2012.)

The diagnosis of ALL is strongly suggested by peripheral blood findings that indicate bone marrow failure. Anemia and thrombocytopenia are seen in most patients. Leukemic cells might not be reported in the peripheral blood in routine laboratory examinations. Many patients with ALL present with total leukocyte counts of <10,000/µL; thrombocytopenia is seen in 75% of patients, and hepatosplenomegaly is seen in 30-40% of patients. In all types of leukemia, CNS symptoms are seen at presentation in 5% of patients (5-10% have blasts in the cerebrospinal fluid [CSF]). Testicular involvement is rarely evident at diagnosis, but prior studies indicate occult involvement in 25% of boys. There is no indication for testicular biopsy.

DIAGNOSIS

The diagnosis of ALL is strongly suggested by peripheral blood findings that indicate bone marrow failure. Anemia and thrombocytopenia are seen in most patients. Leukemic cells might not be reported in the peripheral blood in routine laboratory examinations. Many patients with ALL present with total leukocyte counts of <10,000/µL; thrombocytopenia is seen in 75% of patients, and hepatosplenomegaly is seen in 30-40% of patients. In all types of leukemia, CNS symptoms are seen at presentation in 5% of patients (5-10% have blasts in the cerebrospinal fluid [CSF]). Testicular involvement is rarely evident at diagnosis, but prior studies indicate occult involvement in 25% of boys. There is no indication for testicular biopsy.

an intermittent, low-grade fever. Bone or joint pain, particularly in the lower extremities, may be present. Less commonly, symptoms may be of several months’ duration, may be localized predominantly to the bones or joints, and can include joint swelling. Bone pain is severe and can wake the patient at night. As the disease progresses, signs and symptoms of bone marrow failure become more obvious with the occurrence of pallor, fatigue, exercise intolerance, bruising, or epistaxis, as well as fever, which may be caused by infection or the disease. Organ infiltration can cause lymphadenopathy, hepatosplenomegaly, testicular enlargement, or central nervous system (CNS) involvement (cranial neuropathies, headache, seizures). Respiratory distress may be due to severe anemia or mediastinal node compression of the airways.

On physical examination, findings of pallor, listlessness, purpuric and petechial skin lesions, or mucous membrane hemorrhage can reflect bone marrow failure (see Chapter 493). The proliferative nature of the disease may be manifested as lymphadenopathy, splenomegaly, or, less commonly, hepatomegaly. In patients with bone or joint pain, there may be exquisite tenderness over the bone or objective evidence of joint swelling and effusion. Nonetheless, with marrow involvement, deep bone pain may be present but tenderness will not be elicited. Rarely, patients show signs of increased intracranial pressure that indicate leukemic involvement of the CNS. These include papilledema (see Fig. 493-3), retinal hemorrhages, and cranial nerve palsies. Respiratory distress usually is related to anemia but can occur in patients with an obstructive airway problem (wheezing) as the result of a large anterior mediastinal mass (e.g., in the thymus or nodes). This problem is most typically seen in adolescent boys with T-cell ALL (T-ALL). T-ALL also usually has a higher leukocyte count.

B-lymphoblastic leukemia is the most common immunophenotype, with onset at 1-10 yr of age. The median leukocyte count at presentation is 33,000/µL, although 75% of patients have counts <20,000/µL; thrombocytopenia is seen in 75% of patients, and hepatosplenomegaly is seen in 30-40% of patients. In all types of leukemia, CNS symptoms are seen at presentation in 5% of patients (5-10% have blasts in the cerebrospinal fluid [CSF]). Testicular involvement is rarely evident at diagnosis, but prior studies indicate occult involvement in 25% of boys. There is no indication for testicular biopsy.
DIFFERENTIAL DIAGNOSIS

The diagnosis of leukemia is readily made in the patient with typical signs and symptoms, anemia, thrombocytopenia, and elevated white blood count with blasts present on smear. Elevation of the lactate dehydrogenase is often a clue to the diagnosis of ALL. When only pancytopenia is present, aplastic anemia (congenital or acquired) and myelofibrosis should be considered. Failure of a single cell line, as seen in transient erythroid blastopenia of childhood, immune thrombocytopenia, and congenital or acquired neutropenia, is rarely the presenting feature of ALL. A high index of suspicion is required to differentiate ALL from infectious mononucleosis in patients with acute onset of fever and lymphadenopathy and from juvenile idiopathic arthritis in patients with fever, bone pain but often no tenderness, and joint swelling. These presentations also can require bone marrow examination.

ALL must be differentiated from AML and other malignant diseases that invade the bone marrow and can have clinical and laboratory findings similar to ALL, including neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, and retinoblastoma.

TREATMENT

The single most important prognostic factor in ALL is the treatment: without effective therapy, the disease is fatal. Considerable progress has been made in event-free survival for children with ALL since the 1970s through use of multigagent chemotherapeutic regimens, intensification of therapy, and selection of treatment based upon relapse risk (Fig. 495-2). Survival is also related to age (Fig. 495-3) and subtype (Fig. 495-4).

Risk-directed therapy has become the standard of current ALL treatment and takes into account age at diagnosis, initial white blood cell count, immunophenotypic and cytogenetic characteristics of blast populations, rapidity of early treatment response (i.e., how quickly the leukemic cells can be cleared from the marrow or peripheral blood),

![Figure 495-2](image_url)  
*Figure 495-2* Kaplan-Meier analyses of event-free survival (A) and overall survival (B) in 2,628 children with newly diagnosed ALL. The patients participated in 15 consecutive studies conducted at St. Jude Children’s Research Hospital from 1962-2005. The 5 yr event-free and overall survival estimates (±SE) are shown, except for Study 15, for which preliminary results at 4 yr are provided. The results demonstrate steady improvement in clinical outcome over the past 4 decades. The difference in event-free and overall survival rates has narrowed in the more recent periods, suggesting that relapses or second cancers that occur after contemporary therapy are more refractory to treatment. *(From Pui CH, Evans WE: Treatment of acute lymphoblastic leukemia, N Engl J Med 354:166–178, 2006.)*

![Figure 495-3](image_url)

Higher levels of MRD present at the end of induction suggest a poorer estimate of the burden of leukemic cells present in the marrow. Translocations and other DNA markers contained in leukemic cells or MRD end of the induction phase. Patients in clinical remission can have responded more rapidly. Intensive than the therapy considered necessary for patients who response to initial therapy may be improved by therapy that is more approach, the event-free survival has improved from 30% to 70%. BCR-ABL kinase resulting from the translocation. With this new backbone. Imatinib is an agent specifically designed to inhibit the of Philadelphia chromosome positive ALL with t(9;22) has dramatically of hypodiploidy, the Philadelphia chromosome, and rearrangements, portend a poorer outcome. Other mutations, such as in the IKZF1 gene, have been shown to be associated with a poor prognosis and may become important in treatment algorithms in the future. More favorable characteristics include a rapid response to therapy, hyperdiploidy, trisomy of specific chromosomes (4, 10, and 17), and rearrangements of the ETV6-RUNX1 (formerly TEL-AML1) genes.

The outcome for patients at higher risk can be improved by administration of more intensive therapy despite the greater toxicity of such therapy. Infants with ALL, along with patients who present with specific chromosomal abnormalities, such as t(4;11), have an even higher risk of relapse despite intensive therapy. However, the poor outcome of Philadelphia chromosome positive ALL with t(9;22) has dramatically changed by the addition of imatinib to an intensive chemotherapy backbone. Imatinib is an agent specifically designed to inhibit the BCR-ABL kinase resulting from the translocation. With this new approach, the event-free survival has improved from 30% to 70%. Clinical trials demonstrate that the prognosis for patients with a slower response to initial therapy may be improved by therapy that is more intensive than the therapy considered necessary for patients who respond more rapidly.

Most children with ALL are treated in clinical trials conducted by national or international cooperative groups. Standard treatment involves chemotherapy for 2-3 yr and most achieve remission at the end of the induction phase. Patients in clinical remission can have MRD that can only be detected with specific molecular probes to translocations and other DNA markers contained in leukemic cells or specialized flow cytometry. MRD can be quantitative and can provide an estimate of the burden of leukemic cells present in the marrow. Higher levels of MRD present at the end of induction suggest a poorer prognosis and higher risk of subsequent relapse. MRD of >0.01% on the marrow on day 29 of induction is a significant risk factor for shorter event-free survival for all risk categories, when compared with patients with negative MRD. Therapy for ALL intensifies treatment in patients with evidence of MRD at the end of induction.

Initial therapy, termed remission induction, is designed to eradicate the leukemic cells from the bone marrow. During this phase, therapy is given for 4 wk and consists of vincristine weekly, a corticosteroid such as dexamethasone or prednisone, and usually a single dose of a long-acting, pegylated asparaginase preparation. Patients at higher risk also receive daunomycin at weekly intervals. With this approach, 98% of patients are in remission, as defined by <5% blasts in the marrow and a return of neutrophil and platelet counts to near-normal levels after 4-5 wk of treatment. Intrathecal chemotherapy is always given at the start of treatment and at least once more during induction.

The second phase of treatment, consolidation, focuses on intensive CNS therapy in combination with continued intensive systemic therapy in an effort to prevent later CNS relapses. Intrathecal chemotherapy is given repeatedly by lumbar puncture. The likelihood of later CNS relapse is thereby reduced to <5%, from historical incidence as high as 60%. A small percentage of patients with features that predict a high risk of CNS relapse may receive irradiation to the brain in later phases of therapy. This includes patients who, at the time of diagnosis, have lymphoblasts in the CSF and either an elevated CSF leukocyte count or physical signs of CNS leukemia, such as cranial nerve palsy.

Subsequently, many regimens provide 14-28 wk of therapy, with the drugs and schedules used varying depending on the risk group of the patient. This period of treatment is often termed intensification and includes phases of aggressive treatment (delayed intensification) as well as relatively nontoxic phases of treatment (interim maintenance). Multiantigen chemotherapy, including such medications as cytarabine, methotrexate, asparaginase, and vincristine, is used during these phases to eradicate residual disease.

Finally, patients enter the maintenance phase of therapy, which lasts for 2-3 yr, depending on the protocol used. Patients are given daily mercaptopurine and weekly oral methotrexate, usually with intermittent doses of vincristine and a corticosteroid.

A small number of patients with particularly poor prognostic features, such as those with induction failure or extreme hypodiploidy, may undergo bone marrow transplantation during the first remission.

**Figure 495-4** Kaplan-Meier analysis of event-free survival according to biologic subtype of leukemia. (From Pui CH, Robinson LL, Look AT: Acute lymphoblastic leukaemia, Lancet 371:1030-1042, 2008.)
Adolescents and young adults with ALL have an inferior prognosis compared to children younger than 15 yr old. They often have adverse prognostic factors and require more intensive therapy. Patients in this age group have a superior outcome when treated with pediatric as opposed to adult treatment protocols (Fig. 495-5). Although the explanation for these findings may be multifactorial, it is important that these patients be treated with pediatric treatment protocols, ideally in a pediatric cancer center.

There are genetic polymorphisms of enzymes important in drug metabolism, which may impact both the efficacy and toxicity of chemotherapeutic medications. **Pharmacogenetic testing** of the thiopurine S-methyltransferase (TPMT) gene, which encodes one of the metabolizing enzymes of mercaptopurine, can identify patients who are wild type (normal TPMT enzyme activity), heterozygous (slightly decreased TPMT enzyme activity), or homozygous (low or absent enzyme activity). Decreased TPMT enzyme activity results in an accumulation of a toxic metabolite of mercaptopurine and results in severe myelosuppression, requiring dose reductions of the chemotherapy (see Chapter 35). In the future, treatment may also be stratified by gene expression profiles of leukemic cells. In particular, gene expression arrays induced by exposure to a chemotherapeutic agent can predict which patients have drug-resistant ALL.

**Treatment of Relapse**

The major impediment to a successful outcome is relapse of the disease. Outcomes remain poor among those that relapse, with the most important prognostic indicators being time from diagnosis and the site of relapsed disease. In addition, other factors, such as immunophenotype (T-ALL worse than B-ALL) and age at initial diagnosis, have prognostic significance.

Relapse occurs in the bone marrow in 15-20% of patients with ALL and carries the most serious implications, especially if it occurs during or shortly after completion of therapy. Intensive chemotherapy with agents not previously used in the patient followed by allogeneic stem cell transplantation can result in long-term survival for some patients with bone marrow relapse (see Chapter 135).

The incidence of CNS relapse has decreased to <5% since introduction of preventive CNS therapy. CNS relapse may be discovered at the time of a routine lumbar puncture in the asymptomatic patient. Symptomatic patients with relapse in the CNS usually present with signs and symptoms of increased intracranial pressure and can present with isolated cranial nerve palsies. The diagnosis is confirmed by demonstrating the presence of leukemic cells in the CSF. The treatment includes intrathecal medication and cranial or craniospinal irradiation. Systemic chemotherapy also must be used, because these patients are at high risk for subsequent bone marrow relapse. Most patients with leukemic relapse confined to the CNS do well, especially those in whom the CNS relapse occurs longer than 18 mo after initiation of chemotherapy.

Testicular relapse occurs in less than 2% of boys with ALL, usually after completion of therapy. Such relapse occurs as painless swelling of 1 or both testes. The diagnosis is confirmed by biopsy of the affected testis. Treatment includes systemic chemotherapy and possibly local irradiation. A high proportion of boys with a testicular relapse can be successfully retreated, and the survival rate of these patients is good.

The most current information on treatment of childhood ALL is available in the PDQ (Physician Data Query) on the National Cancer Institute website (http://www.cancer.gov/cancertopics/pdq/treatment/childALL/healthprofessional/).

**SUPPORTIVE CARE**

Close attention to the medical supportive care needs of the patients is essential in successfully administering aggressive chemotherapeutic programs. Patients with high white blood counts are especially prone to tumor lysis syndrome as therapy is initiated. The kidney failure associated with very high levels of serum uric acid can be prevented or treated with allopurinol or urate oxidase. Chemotherapy often produces severe myelosuppression, which can require erythrocyte and platelet transfusion and which always requires a high index of suspicion and aggressive empiric antimicrobial therapy for sepsis in febrile children with neutropenia. Patients must receive prophylactic treatment for *Pneumocystis jiroveci* pneumonia during chemotherapy and for several months after completing treatment.

The successful therapy of ALL is a direct result of intensive and often toxic treatment. However, such intensive therapy can incur substantial academic, developmental, and psychosocial costs for children with ALL and considerable financial costs and stress for their families. Both long-term and acute toxicity effects can occur. An array of cancer care professionals with training and experience in addressing the myriad of problems that can arise is essential to minimize the complications and achieve an optimal outcome.

**PROGNOSIS**

Improvements in therapy and risk stratification have resulted in significant increases in survival rates, with current data showing overall 5 yr survival around 90% (Fig. 495-6). However, survivors are more likely to experience significant chronic medical conditions compared to siblings, including musculoskeletal, cardiac, and neurologic conditions. Overall, long-term management following ALL should be
conducted in a clinic where children and adolescents can be followed by a variety of specialists to address the challenges of these unique patients.

495.2 Acute Myelogenous Leukemia

David G. Tubergen, Archie Bleyer, Erika Friehling, and A. Kim Ritchey

EPIDEMIOLOGY

AML accounts for 11% of the cases of childhood leukemia in the United States; it is diagnosed in approximately 370 children annually. The relative frequency of AML increases in adolescence, representing 36% of cases of leukemia in 15–19 yr olds. One subtype, acute promyelocytic leukemia (APL), is more common in certain regions of the world, but the incidence of the other types is generally uniform. Several chromosomal abnormalities associated with AML have been identified, but no predisposing genetic or environmental factors can be identified in most patients (see Table 495–1). Nonetheless, a number of risk factors have been identified, including ionizing radiation, chemotherapeutic agents (e.g., alkylating agents, epipodophyllotoxin), organic solvents, paroxysmal nocturnal hemoglobinuria, and certain syndromes: Down syndrome, Fanconia anemia, Bloom syndrome, Kostmann syndrome, Shwachman-Diamond syndrome, Diamond-Blackfan syndrome, Li-Fraumeni syndrome, and neurofibromatosis type 1.

CELLULAR CLASSIFICATION

The characteristic feature of AML is that >20% of bone marrow cells on bone marrow aspiration or biopsy touch preparations constitute a fairly homogeneous population of blast cells, with features similar to those that characterize early differentiation states of the myeloid-monocyte-megakaryocyte series of blood cells. Current practice requires the use of flow cytometry to identify cell surface antigens and use of chromosomal and molecular genetic techniques for additional diagnostic precision and to aid the choice of therapy. The WHO has proposed a new classification system that incorporates morphology, chromosome abnormalities, and specific gene mutations. This system provides significant biologic and prognostic information (Table 495–3).

AML, acute myelogenous leukemia; APL, acute promyelocytic leukemia.

CLINICAL MANIFESTATIONS

The production of symptoms and signs of AML is a result of replacement of bone marrow by malignant cells and caused by secondary bone marrow failure. Patients with AML can present with any or all of the findings associated with marrow failure in ALL. In addition, patients with AML present with signs and symptoms that are uncommon in ALL, including subcutaneous nodules or “blueberry muffin” lesions (especially in infants), infiltration of the gingiva (especially in monocytic subtypes), signs and laboratory findings of disseminated intravascular coagulation (especially indicative of APL), and discrete masses, known as chloromas or granulocytic sarcomas. These masses can occur in the absence of apparent bone marrow involvement and typically are associated with a t(8;21) translocation. Chloromas also may be seen in the orbit and epidural space.

DIAGNOSIS

Analysis of bone marrow aspiration and biopsy specimens of patients with AML typically reveals the features of a hypercellular marrow consisting of a monotonous pattern of cells. Flow cytometry and special stains assist in identifying myeloperoxidase-containing cells, thus confirming both the myelogenous origin of the leukemia and the diagnosis. Some chromosomal abnormalities and molecular genetic markers are characteristic of specific subtypes of disease (Table 495–4).

PROGNOSIS AND TREATMENT

Aggressive multiagent chemotherapy is successful in inducing remission in approximately 85–90% of patients. Survival has increased dramatically since the 1970s, when only 15% of newly diagnosed patients survived, compared to a current survival rate of 60–70% with modern therapy (Fig. 495–7). Targeting therapy to genetic markers may be beneficial (see Table 495–4). Up to 5% of patients die of either infection or bleeding before a remission can be achieved. Matched-sibling bone marrow or stem cell transplantation after remission achieves long-term disease-free survival in about two thirds of patients. Continued chemotherapy for patients who do not have a matched sibling donor is
Bibliography

Increased supportive care is needed in patients with AML because the intensive therapy they receive produces prolonged bone marrow suppression with a very high incidence of serious infections, especially *Streptococcal viridans* sepsis and fungal infection. These patients may require prolonged hospitalization, filgrastim (granulocyte colony-stimulating factor), and prophylactic antimicrobials.

The most current information on treatment of AML is available in the PDQ (Physician Data Query) on the National Cancer Institute website (http://www.cancer.gov/cancertopics/pdq/treatment/childAML/healthprofessional/).

### 495.3 Down Syndrome and Acute Leukemia and Transient Myeloproliferative Disorder

*David G. Tubergen, Archie Bleyer, Erika Friehling, and A. Kim Ritchey*

Acute leukemia occurs about 15-20 times more frequently in children with Down syndrome than in the general population (see Chapters 81 and 492). The ratio of ALL to AML in patients with Down syndrome is the same as that in the general population. The exception is during the 1st 3 yr of life, when AML is more common. In children with Down syndrome who have ALL, the expected outcome of treatment is slightly inferior to that for other children, which can be partially explained by a lack of good prognostic characteristics, such as *ETV6-RUNX1* and trisomies, as well as genetic abnormalities that are associated with an inferior prognosis, such as *IKZF1*. Patients with Down syndrome demonstrate a remarkable sensitivity to methotrexate and other antimetabolites, which can result in substantial toxicity if standard doses are administered. In AML, however, patients with Down syndrome have much better outcomes than non–Down syndrome children, with a >80% long-term survival rate. After induction therapy, these patients receive therapy that is less intensive to achieve better results.

Approximately 10% of neonates with Down syndrome develop a transient leukemia or myeloproliferative disorder characterized by high leukocyte counts, blast cells in the peripheral blood, and associated anemia, thrombocytopenia, and hepatosplenomegaly. These features usually resolve within the 1st 3 mo of life. Although these neonates can require temporary transfusion support, they do not require chemotherapy unless there is evidence of life-threatening complications. However, patients who have Down syndrome and who develop this transient leukemia or myeloproliferative disorder require close follow-up, because 20-30% will develop typical leukemia (often acute megakaryocytic leukemia) by 3 yr of life (mean onset, 16 mo). *GATA1* mutations (a transcription factor that controls megakaryopoiesis) are present in blasts from patients with Down syndrome who have

### 495.4 Chronic Myelogenous Leukemia

David G. Tubergen, Archie Bleyer, Erika Friehling, and A. Kim Ritchey

CML is a clonal disorder of the hematopoietic tissue that accounts for 2-3% of all cases of childhood leukemia. Approximately 99% of the cases are characterized by a specific translocation, t(9;22)(q34;q11), known as the Philadelphia chromosome, resulting in a BCR-ABL fusion protein.

The presenting symptoms of CML are nonspecific and can include fever, fatigue, weight loss, and anorexia. Splenomegaly also may be present, resulting in pain in the left upper quadrant of the abdomen. The diagnosis is suggested by a high white blood cell count with myeloid cells at all stages of differentiation in the peripheral blood and bone marrow and is confirmed by cytogenetic and molecular studies that demonstrate the presence of the characteristic Philadelphia chromosome and the BCR-ABL gene rearrangement. This translocation, although characteristic of CML, is also found in a small percentage of patients with ALL.

The disease is characterized by an initial chronic phase in which the malignant clone produces an elevated leukocyte count with a predominance of mature forms but with increased numbers of immature granulocytes. In addition to leukocytosis, blood counts can reveal mild anemia and thrombocytopenia. Typically, the chronic phase terminates 3-4 yr after onset, when the CML moves into the accelerated or “blast crisis” phase. At this point, the blood counts rise dramatically and the clinical picture is indistinguishable from acute leukemia. Additional manifestations can occur, including neurologic symptoms from hyperleukocytosis, which causes increased blood viscosity with decreased CNS perfusion.

Imatinib (Gleevec), an agent designed specifically to inhibit the BCR-ABL tyrosine kinase, has been used in adults and children and has shown an ability to produce major cytogenetic responses in >70% of patients (see Table 494-1). Experience in children suggests it can be used safely with results comparable to those seen in adults. Second-generation tyrosine kinase inhibitors, such as dasatinib, have improved remission rates in adults and are now included in the first-line therapy in that population while they are being studied in children. While waiting for a response to the tyrosine kinase inhibitor, disabling or threatening signs and symptoms of CML can be controlled during the chronic phase with hydroxyurea, which gradually returns the leukocyte count to normal. Prolonged morphologic and cytogenetic responses are expected, but the opportunity for cure is enhanced by human leukocyte antigen–matched family donor allogeneic stem cell transplant, with up to 80% of children achieving a cure.

Bibliography is available at Expert Consult.

### 495.5 Juvenile Myelomonocytic Leukemia

David G. Tubergen, Archie Bleyer, Erika Friehling, and A. Kim Ritchey

JMML, formerly termed juvenile CML, is a clonal proliferation of hematopoietic stem cells that typically affects children younger than 2 yr of age. JMML is rare, constituting <1% of all cases of childhood leukemia. Patients with this disease do not have the Philadelphia chromosome that is characteristic of CML. Patients with JMML present with rashes, lymphadenopathy, splenomegaly, and hemorrhagic manifestations. Analysis of the peripheral blood often shows an elevated leukocyte count with increased monocytes, thrombocytopenia, and anemia with the presence of erythroblasts. The bone marrow shows a myelodysplastic pattern, with blasts accounting for <20% of cells. Most patients with JMML have been found to have mutations that lead to activation of the RAS oncogene pathway including NFI and PTPN11. Patients with neurofibromatosis type 1 and Noonan syndrome have a predilection for this type of leukemia, since they have germline mutations involved in RAS signaling. Therapeutic reports are largely anecdotal. Stem cell transplantation offers the best opportunity for cure but much less so than for classic CML.

Bibliography is available at Expert Consult.

### 495.6 Infant Leukemia

David G. Tubergen, Archie Bleyer, Erika Friehling, and A. Kim Ritchey

Approximately 2% of cases of leukemia during childhood occur before the age of 1 year. In contrast to older children, the ratio of ALL to AML is 2:1. Leukemic clones have been noted in cord blood at birth before symptoms appear, and in 1 case the same clone was noted in maternal cells (maternal to fetal transmission). Chromosome translocations can also occur in utero during fetal hematopoiesis, thus leading to malignant clone formation.

Several unique biologic features and a particularly poor prognosis are characteristic of ALL during infancy. More than 80% of the cases demonstrate rearrangements of the MLL gene, found at the site of the 11q23 band translocation, the majority of which are the t(4;11). This subset of patients largely accounts for the very high relapse rate. These patients often present with hyperleukocytosis and extensive tissue infiltration producing organomegaly, including CNS disease. Subcutaneous nodules, known as leukemia cutis, and tachypnea caused by diffuse pulmonary infiltration by leukemic cells are observed more often in infants than in older children. The leukemic cell morphology is usually that of large irregular lymphoblasts, with a phenotype

negative for the CD10 (common ALL antigen) marker (pro-B) unlike most older children with B-ALL who are CD10+. Very intensive chemotherapy programs, including stem cell transplantation, are being explored in infants with MLL gene rearrangements, but none has yet proved satisfactory. Infants with leukemia who lack the 11q23 rearrangements have a prognosis similar to that of older children with ALL.

Infants with AML often present with CNS or skin involvement and have a subtype known as acute myelomonocytic leukemia. The treatment may be the same as that for older children with AML, with similar outcome. Meticulous supportive care is necessary because of the young age and aggressive therapy needed in these patients.

Bibliography

Lymphoma is the third most common cancer among U.S. children (age 14 yr or younger), with an annual incidence of 15 cases per 1 million children. It is the most common cancer in adolescents, accounting for >25% of newly diagnosed cancers in persons 15-19 yr old. The 2 broad categories of lymphoma, Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL), have different clinical manifestations and treatments.*

Hodgkin lymphoma (HL) is a malignant process involving the lymphoreticular system that accounts for 6% of childhood cancers. In the United States, HL accounts for approximately 5% of cancers in persons 14 yr of age or younger; it accounts for approximately 15% of cancers in adolescents (15-19 yr of age), making HL the most common malignancy in this age group.

**EPIDEMIOLOGY**

The worldwide incidence of HL is approximately 2-4 new cases/100,000 population/yr; there is a bimodal age distribution, with peaks at 15-35 yr of age and again after 50 yr. It is the most common cancer seen in adolescents and young adults, and the third most common in children younger than the age of 15 yr. In developing countries, the early peak tends to occur prior to adolescence. A male:female predominance is found among young children, but lessens with age. Infectious agents may be involved, such as human herpesvirus 6, cytomegalovirus, and Epstein-Barr virus (EBV). The role of EBV is supported by prospective serologic studies. Infection with EBV confers a 4-fold higher risk of developing HL and may precede the diagnosis by years. EBV antigens have been demonstrated in HL tissues, particularly type II latent membrane proteins 1 and 2, although EBV status is not thought to be prognostic of outcome.

**PATHOGENESIS**

The Reed-Sternberg (RS) cell, a pathognomonic feature of HL, is a large cell (15-45 μm in diameter) with multiple or multilobulated nuclei. This cell type is considered the hallmark of HL, although similar cells are seen in infectious mononucleosis, NHL, and other conditions. The RS cell is clonal in origin and arises from the germinal center B cells but typically has lost most B-cell gene expression and function. There is no single simple genetic aberration that leads to malignant transformation of the RS cell, but rather a combination of somatic mutations, chromosomal instability, and complex chromosomal rearrangements have been reported with no particular pattern or frequency. This typically leads to cell regulation defects such as constitutive activation of the nuclear factor-κB pathway or abnormal regulation of the Bcl-2 family of proteins. HL is characterized by a variable number of RS cells surrounded by an inflammatory infiltrate of lymphocytes, plasma cells, and eosinophils in different proportions, depending on the HL histologic subtype. The interaction between the RS cell and these background inflammatory cells with their associated cytokine release is important in the development and progression of HL. Reactive infiltration of eosinophils and CD68+ macrophages, and increased concentrations of cytokines, such as interleukins 1 and 6 and tumor necrosis factor, are all associated with an unfavorable prognosis, including advanced stage, the presence of “B” symptoms, decreased response to therapy, and reduced survival. In addition, evidence of CD8+ T cells surrounding the RS cell offers evidence of an important role in T-cell promotion of malignant cell survival, perhaps through the CD30 and CD40 ligands found on RS cells. Other features that distinguish the histologic subtypes include various degrees of fibrosis and the presence of collagen bands, necrosis, or malignant reticular cells (Fig. 496-1). The distribution of subtypes varies with age.

The Revised World Health Organization Classification of Lymphoid Neoplasms (Table 496-1) includes 2 modifications of the older Rye system. HL appears to arise in lymphoid tissue and spread to adjacent lymph node areas in a relatively orderly fashion. Hematogenous spread also occurs, leading to involvement of the liver, spleen, bone, bone marrow, or brain, and is usually associated with systemic symptoms.

**CLINICAL MANIFESTATIONS**

Patients commonly present with painless, nontender, firm, rubbery, or supravacular lymphadenopathy and usually some degree of mediastinal involvement. Clinically detectable hepatosplenomegaly is rarely encountered. Depending on the extent and location of nodal and extranodal disease, patients may present with symptoms and signs of airway obstruction (dyspnea, hypoxia, cough), pleural or pericardial effusion, hepatocellular dysfunction, or bone marrow infiltration (anemia, neutropenia, or thrombocytopenia). Disease manifesting below the diaphragm is rare and occurs in approximately 3% of all cases. Systemic symptoms, classified as B symptoms that are considered important in staging, are unexplained fever >38°C (100.4°F), weight loss >10% total body weight over 6 mo, and drenching night sweats. Less common and not considered of prognostic significance are symptoms of pruritus, lethargy, anorexia, or pain that worsens after ingestion of alcohol. Patients also exhibit immune system abnormalities that often persist during and after therapy.

**DIAGNOSIS**

Any patient with persistent, unexplained lymphadenopathy unassociated with an obvious underlying inflammatory or infectious process should undergo chest radiography to identify the presence of a large mediastinal mass before undergoing lymph node biopsy. Formal excisional biopsy is preferred over needle biopsy to ensure that adequate tissue is obtained, both for light microscopy and for appropriate immunohistochemical and molecular studies. Once the diagnosis of HL is established, extent of disease (stage) should be determined to allow selection of appropriate therapy (Table 496-2). Evaluation includes history, physical examination, and imaging studies, including chest radiograph; CT scans of the neck, chest, abdomen, and pelvis; and positron emission tomography (PET) scan. Laboratory studies should include a complete blood cell count to identify abnormalities that might suggest marrow involvement; erythrocyte sedimentation rate; and measurement of serum ferritin, which is of some prognostic

*The absence or presence of fever >38°C (100.4°F) for 3 consecutive days, drenching night sweats, or unexplained loss of >10% of body weight in the 6 mo preceding admission are to be denoted in all cases by the suffix letter A or B, respectively.

significance and, if abnormal at diagnosis, serves as a baseline to evaluate the effects of treatment. A chest radiograph is particularly important for measuring the size of the mediastinal mass in relation to the maximal diameter of the thorax (Fig. 496-2). This determines “bulk” disease and becomes prognostically significant. Chest CT more clearly defines the extent of a mediastinal mass if present and identifies hilar nodes and pulmonary parenchymal involvement, which may not be evident on chest radiographs. Bone marrow aspiration and biopsy should be performed to rule out advanced disease. Bone scans are performed in patients with bone pain and/or elevation of alkaline phosphatase. Gallium scan can be particularly helpful in identifying areas of increased uptake, which can then be reevaluated at the end of treatment. Fluorodeoxyglucose PET imaging has advantages over gallium scanning, as it is a 1-day procedure with higher resolution, better dosimetry, less intestinal activity, and the potential to quantify disease. PET scans are being evaluated as a prognostic tool in HL, enabling therapy to be reduced in those predicted to have a good outcome.

The staging classification currently used for HL was adopted at the Ann Arbor Conference in 1971 and was revised in 1989 (see Table 496-2). HL can be subclassified into A or B categories: A is used to identify asymptomatic patients and B is for patients who exhibit any B symptoms. Extralymphatic disease resulting from direct extension of an involved lymph node region is designated by category E. A complete response in HL is defined as the complete resolution of disease on clinical examination and imaging studies or at least 70-80% reduction of disease and a change from initial positivity to negativity on either gallium or PET scanning because residual fibrosis is common.

**TREATMENT**

Multiple agents allow different mechanisms of action to have non-overlapping toxicities so that full doses can be given to each patient.

Chemotherapy and radiation therapy are both effective in the treatment of HL. Treatment of HL in pediatric patients is risk adapted and involves the use of combined chemotherapy with or without low-dose involved-field radiation therapy based on response. Treatment is determined largely by disease stage, presence or absence of B symptoms, and the presence of bulky nodal disease. Radiation therapy alone, once given at higher doses, initially resulted in prolonged remission and cure rates in patients with low-stage HL. However, this treatment also caused significant long-term morbidity in pediatric patients, including growth retardation, thyroid dysfunction, and cardiac and pulmonary toxicity. The development of effective multiagent combination chemotherapy was a major milestone in the treatment of HL resulting in a complete response rate of 70-80% and cure rate of 40-50% in patients with advanced-stage disease. However, this regimen also led to significant acute and long-term toxicity. The desire to reduce side effects and morbidity has stimulated attempts to reduce the intensity of chemotherapy as well as radiation dose and volume. Newer combinations of chemotherapy have reduced the risk of secondary cancers. Also, current radiation therapy utilizes lower amounts of overall radiation in addition to narrowing the radiation treatment field to either involved-field or even involved-node irradiation. The current Children's Oncology Group trials are investigating whether radiation therapy can be eliminated altogether in patients who have a very good rapid early response to pre-radiation induction chemotherapy.

Chemotherapy agents commonly used to treat children and adolescents with HL include cyclophosphamide, procarbazine, vincristine or vinblastine, prednisone or dexamethasone, doxorubicin, bleomycin, dacarbazine, etoposide, methotrexate, and cytosine arabinoside. The combination chemotherapy regimens in current use are based on COPP (cyclophosphamide, vincristine [Oncovin], procarbazine, and prednisone) or ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine), with the addition of prednisone, cyclophosphamide, and etoposide (ABVE-PC and BEACOPP) or BAVD (brentuximab vedotin, doxorubicin [Adriamycin], vincristine, dacarbazine) in various combinations for intermediate- and high-risk groups (Table 496-3). "Risk-adapted" protocols are based on both staging criteria and rapidity of response to initial chemotherapy. The aim is to reduce total drug doses and treatment duration and to eliminate radiation therapy if possible.

Agents such as those that disrupt the nuclear factor-κB pathway or monoclonal antibodies that target RS tumor cells as well as the benign reactive cells that surround them are currently being investigated. Ongoing clinical trials report encouraging results with the use of anti-CD20 antibody (rituximab), particularly in nodular lymphocyte-predominant Hodgkin lymphoma where trials in relapsed disease have shown an overall response rate of 94%. In addition, anti-CD30 agents

are being used that are targeted to the RS cells themselves, where CD30 is abundantly expressed. Brentuximab vedotin is an antibody–drug conjugate that is now FDA approved to treat Hodgkin lymphoma. It combines the chimeric anti-CD30 antibody brentuximab linked to the antimitotic agent monomethyl auristatin E. This agent shows impressive efficacy as single-agent therapy in refractory HL and is currently being tested as part of upfront therapy combined with chemotherapy in patients with newly diagnosed disease. EBV-specific cytotoxic T lymphocytes (CTLs) can also be generated from allogeneic donors for patients with advanced HL (Fig. 496-3). In clinical trials, these show promising results, with enhanced antiviral activity and stabilization of disease even though all patients continue to have persistent disease. EBV-CTLs have been developed and are currently being investigated. These enhanced EBV-CTLs are designed to be latent membrane protein 1/2 specific and can be generated from second (in the case of bone marrow transplant recipients) or even third-party donors for patients with refractory disease. These newer approaches represent an exciting new direction in adoptive cellular tumor immunology, and it remains to be determined whether CTLs will have improved cytotxicity that can overcome inhibitory signals.

**RELAPSE**

Most relapses occur within the 1st 3 yr after diagnosis, but relapses as late as 10 yr have been reported. Relapse cannot be predicted accurately with this disease. Poor prognostic features include tumor bulk, stage at diagnosis, extralymphatic disease, and presence of B symptoms. Patients who achieve an initial chemosensitive response but relapse or progress less than 12 mo from diagnosis are candidates for myeloablative chemotherapy and autologous stem cell transplantation with or without the addition of radiation therapy. Retrospective studies show a significant decrease in relapse in patients with HL following autologous vs autologous stem cell transplant (18% vs 41%). Although in earlier studies there was no improvement in overall survival owing to a high transplantation-related mortality, reduced-intensity conditioning or nonmyeloablative regimens are successful at reducing regimen-related mortality and mortality associated with myeloablative allogeneic stem cell transplantation while still achieving a strong graft-versus-HL effect. For more difficult-to-treat refractory cases, agents such as Zevalin or Bexxar are being trialed, often in combination with stem cell transplantation strategies. Both are monoclonal anti-CD20 antibodies to which a radioactive isotope is directly linked. Clinical trials show each to be more effective than rituximab in NHL patients, and there is some interest in studying their use in the CD20 subpopulation of HL patients.

**PROGNOSIS**

With the use of current therapeutic regimens, patients with favorable prognostic factors and early-stage disease have an event-free survival (EFS) of 85-90% and an overall survival (OS) at 5 yr of >95%. Patients with advanced-stage disease have slightly lower EFS (80-85%) and OS (90%), respectively, although OS has approached 100% with dose-intense chemotherapy (Table 496-4). Prognosis after relapse depends

---

**Figure 496-3 Epstein-Barr virus (EBV)-specific cytotoxic T lymphocyte (CTL) production.** EBV-transformed B-cell lymphoblastoid cell line (LCLs) are prepared from the CTL donor by infection of peripheral blood mononuclear cells (PBMCs) with a clinical-grade laboratory strain of EBV (B95-8) in the presence of cyclosporine. Once the LCL is established (about 6 wk), it is irradiated an used to stimulate PBMCs from the same donor at a 40:1 ratio of PBMC:LCL. From 9-12 days later and weekly thereafter, the T cells are restimulated with the LCL at a 4:1 ratio. Interleukin 2 is added 3 days after the second stimulation and twice weekly thereafter. The CTLs should kill autologous LCLs but not autologous phytohemagglutinin blasts. Their specificity is donor dependent and they may have specificity for any of the 10 latency-associated antigens and/or for early lytic cycle proteins that are expressed by a small fraction of the LCLs, which are grown in acyclovir to prevent the production of infectious virus by blocking the viral thymidine kinase. (Adapted from Bollard CM, Rooney CM, Heslop HE. T-cell therapy in the treatment of post-transplant lymphoproliferative disease. Nat Rev Clin Oncol 9:510–519, 2012, Fig. 2.)

on the time from completion of treatment to recurrence, site of relapse (nodal vs extranodal), and presence of B symptoms at relapse). Patients whose disease relapses >12 mo after chemotherapy alone or combined-modality therapy have the best prognosis, and their relapses usually respond to additional standard therapy, resulting in a long-term survival of 60-70%. A myeloablative autologous stem cell transplantation in patients with refractory disease or relapse within 12 mo of therapy results in a long-term survival rate of only 40-50%. Allogeneic stem cell transplantation has shown promise in patients with poor risk features at relapse/progression.

Bibliography is available at Expert Consult.

### 496.2 Non-Hodgkin Lymphoma

Jessica Hochberg, Lisa Giulino-Roth, and Mitchell S. Cairo

Non-Hodgkin lymphoma (NHL) accounts for approximately 60% of lymphomas in children and is the second most common malignancy in patients age 15-35 yr. The annual incidence of pediatric NHL in the United States is 750-800 cases/yr. In contrast to adult NHL, which is typically indolent, pediatric NHL is usually high grade and aggressive. Although more than 70% of patients present with advanced disease, the prognosis has improved dramatically, with survival rates of 90-95% for localized disease and 70-95% with advanced disease.

**EPIDEMIOLOGY**

Although most children and adolescents with NHL present with de novo disease, a small number of patients have NHL secondary to specific etiologies, including inherited or acquired immune deficiencies (e.g., severe combined immunodeficiency syndrome, Wiskott-Aldrich syndrome), viruses (e.g., HIV, EBV), and as part of genetic syndromes (e.g., ataxia-telangiectasia, Bloom syndrome). However, most children in North America and Europe in whom NHL develops have no obvious genetic or environmental etiology.

**PATHOGENESIS**

The 4 major pathologic subtypes of childhood and adolescent NHL are lymphoblastic lymphoma (LBL), Burkitt lymphoma (BL), diffuse large B-cell lymphoma (DLBCL), and anaplastic large cell lymphoma.
Chapter 496  •  Lymphoma 2449.e1

Bibliography
lymphoma (ALCL; Figs. 496-4 and 496-5). LBL arises from immature B or T lymphocytes whereas BL, DLBCL, and ALCL are mature B- or T-cell neoplasms. DLBCL is further divided into several subtypes: the germinal center B-cell-like, which carries a favorable prognosis and accounts for the vast majority of pediatric cases of DLBCL, and the subtypes with poorer prognosis, activated B-cell-like and primary mediastinal B-cell subtypes. The cell of origin varies among NHL histologic subtypes. Almost all BLs and DLBCLs are of B-cell origin; 90% cases of LBL are of T-cell origin and 10% of B-cell origin; and 70% of cases of ALCL are of T-cell origin, 20% are of null-cell origin, and 10% are of B-cell origin. Cellular surface markers can aid in differentiating NHL subtypes and also present opportunities for targeted treatments. BL and DLBCL frequently express the B-cell antigens CD19, CD20, and CD22. ALCL, in contrast, expresses the CD30 antigen. Some pathologic subtypes have specific cytogenetic aberrations. Children with BL commonly have a t(8;14) translocation (90%) or, less commonly, a t(2;8) or t(8;22) translocation (10%). Children with BL who have a 13q deletion or complex karyotype have a poor prognosis. Those with DLBCL may have a t(8;14) translocation (30%) and often have a complex (80%) and aneuploid (80%) karyotype. Patients with ALCL commonly have a t(2;5) translocation (90%), which results in the formation of a fusion gene encoding the constitutively active nucleophosmin-anaplastic lymphoma kinase tyrosine kinase. Variant anaplastic lymphoma kinase (ALK) translocations, all with a breakpoint at 2p23, have also been reported. T-cell LBL harbors many of the same cytogenetic abnormalities as T-cell acute lymphoblastic leukemia (T-ALL), including rearrangements with breakpoints at 14q11.2 involving the T-cell receptor, and t(5;14) translocation (20%), which does not involve the 14q11.2 breakpoint.

Genomic studies have offered insights into NHL pathogenesis as well as elucidated potential targets for novel therapies. Gene expression profiling of T-LBL and T-ALL has implicated the activation of oncogenic transcription factors as a result of aberrant T-cell receptor gene rearrangement. One of the most frequently activated signaling pathways is NOTCH1, which may be amenable to therapeutic targeting with γ-secretase inhibitors. In BL and DLBCL, extensive genomic work has identified unique gene expression signatures that differentiate these 2 mature B-cell neoplasms. In addition, next-generation sequencing of BL has identified genetic lesions in TCF3 and ID3, which lead to activation of the AKT/PI3 kinase pathway. Other genetic lesions that have been described in BL include loss of function of the chromatin remodeling genes ARID1A and SMARCA4. Importantly, many of these alterations are potentially targetable by agents that are currently in development.

CLINICAL MANIFESTATIONS
The clinical manifestations of childhood and adolescent NHL depend primarily on pathologic subtype and sites of involvement. The staging system used for NHL is the St. Jude/Murphy classification (Table 496-5), although this classification schema is currently under an

E-H from Giulino-Roth, Cesarman E: Molecular biology of Burkitt lymphoma. In Robertson ES, editor, Burkitt’s lymphoma. New York, 2012, Springer.)
The primary modality of treatment for childhood and adolescent NHL is multiagent systemic chemotherapy with intrathecal chemotherapy (see Table 496-4). Surgery is used mainly for diagnosis. Radiation therapy is used only in special circumstances, such as CNS involvement in LBL or, in the presence of acute superior mediastinal syndrome or paraplegias. Newly diagnosed patients, especially those with BL and LBL, are at high risk for TLS. These patients require vigorous hydration, frequent electrolyte monitoring, and either a xanthine oxidase inhibitor (allopurinol, 10 mg/kg/day PO divided into 3 doses daily) or recombinant urate oxidase (rasburicase, 0.2 mg/kg/day IV once daily for up to 5 days). Recombinant urate oxidase is preferred in patients with a high risk of tumor lysis. Frequently, only a single dose is needed; however, repeat doses can be given if a subsequent rise in uric acid is seen.

**TREATMENT**

The primary modality of treatment for childhood and adolescent NHL is multiagent systemic chemotherapy with intrathecal chemotherapy (see Table 496-4). Surgery is used mainly for diagnosis. Radiation therapy is used only in special circumstances, such as CNS involvement in LBL or, in the presence of acute superior mediastinal syndrome or paraplegias. Newly diagnosed patients, especially those with BL and LBL, are at high risk for TLS. These patients require vigorous hydration, frequent electrolyte monitoring, and either a xanthine oxidase inhibitor (allopurinol, 10 mg/kg/day PO divided into 3 doses daily) or recombinant urate oxidase (rasburicase, 0.2 mg/kg/day IV once daily for up to 5 days). Recombinant urate oxidase is preferred in patients with a high risk of tumor lysis. Frequently, only a single dose is needed; however, repeat doses can be given if a subsequent rise in uric acid is seen.

**Burkitt Lymphoma and Diffuse Large B-cell Lymphoma**

Pediatric BL and DLBCL are treated with similar chemotherapy regimens, which are designed for mature B-NHL. Regimens vary based on stage and risk stratification. For patients with localized disease, multiagent chemotherapy is given over a 6 wk to 6 mo period and the prognosis is excellent. In the international FAB/LMB 96 (French-American-British Lymphoma, mature B cell) trial, patients with
localized, completely resected disease received 2 cycles of COPAD (cyclophosphamide, vincristine, prednisone, and doxorubicin) resulting in a 4 yr OS of 99%. Advanced disease is usually treated with a 4-6 mo regimen of multiagent chemotherapy, such as FAB/LMB 96 protocol therapy or NHL-BFM (Berlin-Frankfurt-Munich) 95 protocol therapy with an OS of 79-90%. A subset of patients that likely require a different treatment approach are those with primary mediastinal B-cell lymphoma (PMBCl). PMBCl is a histologic subtype that represents 2% of mature B-NHLs. Pediatric patients with PMBCl have an inferior outcome when treated with standard mature B-NHL protocols (EFS of only 66%). Alternative treatment strategies, including rituximab and other novel agents, may be of benefit to this group.

Rituximab is a monoclonal antibody directed at CD20 that improves outcomes in adult patients with B-NHL. As nearly all pediatric BLs and DLBCLs express CD20, rituximab has been examined in pediatric B-NHL; however, the efficacy in this setting is not yet known. A window study of rituximab given to pediatric patients with newly diagnosed BL and DLBCL demonstrated its activity as a single agent with a response rate of 41%. Additionally, a Children's Oncology Group study examined the safety and pharmacokinetics of rituximab when added to standard chemotherapy for intermediate-risk patients. Rituximab was found to be safe, and survival in this cohort was the best reported to date (3 yr OS of 95%). In a similar cohort of CNS-positive patients, the addition of rituximab to the chemotherapy backbone resulted in a 93% EFS.

Lymphoblastic Lymphoma
Localized or advanced LBL requires 12-24 mo of therapy including chemotherapy, intrathecal therapy, and cranial radiation in some cases. The best results in advanced LBL have been obtained using the NHL-BFM 90 protocol, which uses therapeutic approaches similar to those for childhood acute leukemia, including induction, consolidation, interim maintenance, and reinduction (advanced disease only) phases as well as a year-long maintenance phase with 6-mercaptopurine and methotrexate. Studies have attempted to determine whether cranial radiation can be omitted, with promising results; however, the sample size in these studies is small. For patients with relapsed disease, the outcome is poor (OS of 10%) and novel treatments are needed. Nalerebin is a purine analog with significant T-lymphocyte toxicity; nalerebin has been investigated in T-LBL. Nalerebin is currently undergoing investigation in high-risk patients with T-ALL and T-LBL.

Anaplastic Large Cell Lymphoma
For patients who present with localized disease, surgical resection alone is sufficient. The majority of patients, however, have advanced disease, which requires multiagent chemotherapy. Various chemotherapy regimens have been studied with similar outcomes and survival ranging from 70-79%. CNS prophylaxis consists of intrathecal chemotherapy; however, it may be possible to omit this with the substitution of high-dose methotrexate. CNS disease, although rare, can be seen and is treated with intrathecal chemotherapy and cranial radiation.

Two novel targeted agents have shown substantial promise in early-phase trials in ALCL. The CD30 antibody–drug conjugate brentuximab and the ALK inhibitor crizotinib both have impressive activity and minimal toxicity in patients with relapsed ALCL. Given the high efficacy and low toxicity profile, it may be possible to use these agents in newly diagnosed patients to eliminate the reliance on and toxicity of conventional chemotherapy.

Relapsed Non-Hodgkin Lymphoma
Patients with NHL in whom progressive or relapsed disease develops require reinduction chemotherapy and either allogeneic or autologous stem cell transplantation (SCT). The specific reinduction regimen or transplantation type depends on the pathologic subtype, previous therapy, site of recurrence, and stem cell donor availability. Although there are no randomized trials examining autologous vs allogeneic SCT for relapsed NHL, data from retrospective studies suggest that outcomes are similar with the exception of LBL and ALCL where allogeneic SCT is superior, perhaps because of a graft-vs-lymphoma effect.

As relapsed NHL can be difficult to treat, efforts have been made to identify those patients at higher risk of relapse to tailor the initial therapy. The measurement of minimal residual disease may serve as a prognostic marker and aid in risk stratification. Minimal residual disease is prognostic in ALCL and LBL. In ALCL, there is also evidence that a humoral response to the ALK kinase can be used to predict outcome with a superior outcome in patients who mount an antibody titer to ALK. Minimal residual disease measurement in intermediate-risk B-NHL is feasible and is currently being evaluated in an international trial.

COMPLICATIONS
Patients receiving multiagent chemotherapy for advanced disease are at acute risk for serious mucositis, infections, cytopenias that require red blood cell and platelet blood product transfusions, electrolyte imbalances, and poor nutrition. Long-term complications include the risk of growth retardation, cardiac toxicity, gonadal toxicity with infertility, and secondary malignancies.

PROGNOSIS
The prognosis is excellent for most forms of childhood and adolescent NHL (see Table 496-4). Patients with localized disease have a 90-100% chance of survival, and those with advanced disease have a 70-95% chance of survival. As outcomes for pediatric patients with NHL have improved substantially, the focus has now shifted to minimizing the long-term toxicity of therapy. Novel targeted agents are desirable as they have the potential to improve outcomes and decrease the reliance on toxic conventional chemotherapy.

496.3 Late Effects in Children and Adolescents with Lymphoma

Jessica Hochberg, Lisa Giulino-Roth, and Mitchell S. Cairo

The majority of patients with newly diagnosed HL and NHL have OS rates above 90%. There are approximately 270,000 survivors of childhood cancer in the United States, which equates to about 1 of every 640 adults between the ages of 20 and 40 yr. However, this survival has often been achieved at the expense of an increased relative risk of long-term complications, including solid tumors, leukemia, cardiac disease, pulmonary complications, thyroid disease, and infertility. An analysis of more than 1,000 long-term childhood NHL survivors found increased rates of death >20 yr after treatment. A review of Surveillance, Epidemiology and End Results data over a 25 yr follow-up period demonstrates that the relative survival curves do not plateau after 10 yr following diagnosis of HL but, rather, accelerate. This finding highlights the importance of late morbidity and mortality among survivors of lymphoma. The first Childhood Cancer Survivor Study, a retrospective cohort study of 10,397 cancer survivors, shows that 62.3% of survivors report at least 1 chronic condition, with 27.5% reporting severe or life-threatening conditions. The survivor's adjusted relative risk of a severe or life-threatening chronic condition, compared with that of a sibling, was 8.2 (95% confidence interval, 6.9-9.7). When disease-specific health outcomes were looked at, both HL and NHL were found to be associated with a cumulative incidence of chronic health conditions approaching 70-80%, with severe conditions being reported in close to 50% of HL survivors (Fig. 496-6).
Figure 496-6 Percentage of attributable proportions of overall mortality risk in survivors of childhood cancer. (Adapted from Yeh JM, Nekhlyudov L, Goldie SJ, et al: A model-based estimate of cumulative excess mortality in survivors of childhood cancer, Ann Intern Med 152[7]:409-417, 2010.)
Primary central nervous system (CNS) tumors are a heterogeneous group of diseases that are, collectively, the second most common malignancy in childhood and adolescence. The overall mortality among this group approaches 30%. Patients with CNS tumors have the highest morbidity—primarily neurologic—of all children with malignancies. Outcomes have improved over time with innovations in neurosurgery and radiation therapy as well as the introduction of chemotherapy as a therapeutic modality. The treatment approach for these tumors is multimodal. Surgery with complete resection, if feasible, is the foundation, with radiation therapy and chemotherapy utilized according to the diagnosis, patient age, and other factors.

**ETIOLOGY**

The etiology of pediatric brain tumors is not well defined. A male predominance is noted in the incidence of medulloblastoma and ependymoma. Familial and hereditary syndromes associated with an increased incidence of brain tumors account for approximately 5% of cases (Table 497-1). Cranial exposure to ionizing radiation also is associated with a higher incidence of brain tumors. There are sporadic reports of brain tumors within families without evidence of a heritable syndrome. The molecular events associated with tumorigenesis of pediatric brain tumors are not known.

**EPIDEMIOLOGY**

Approximately 4,600 primary brain tumors are diagnosed each year in children and adolescents in the United States, with an overall annual incidence of approximately 47 cases/1 million children younger than 20 yr of age. The incidence of CNS tumors is highest in infants and children 5 yr of age or younger (approximately 52 cases/1 million children).

**PATHOGENESIS**

More than 100 histologic categories and subtypes of primary brain tumors are described in the World Health Organization (WHO) classification of tumors of the CNS. In children 0-14 yr of age, the most common tumors are pilocytic astrocytomas (PAs) and medulloblastoma/primitive neuroectodermal tumors (PNETs). In adolescents (15-19 yr), the most common tumors are pituitary tumors and PAs (Fig. 497-1).

The Surveillance, Epidemiology, and End Results program reported a slight predominance of infratentorial tumor location (43.2%), followed by the supratentorial region (40.9%), spinal cord (4.9%), and multiple sites (11%) (Fig. 497-2, Table 497-2). There are age-related differences in primary location of tumor. During the 1st yr of life, supratentorial tumors predominate and include, most commonly, choroid plexus complex tumors and teratomas. In children 1-10 yr of age, infratentorial tumors predominate, owing to the high incidence of juvenile PA and medulloblastoma. After 10 yr of age, supratentorial tumors again predominate, with diffuse astrocytomas most common. Tumors of the optic pathway and hypothalamic region, the brainstem, and the pineal—midbrain region are more common in children and adolescents than in adults.

**CLINICAL MANIFESTATIONS**

The clinical presentation of the patient with a brain tumor depends on the tumor location, the tumor type, and the age of the child. Signs and symptoms are related to obstruction of cerebrospinal fluid (CSF) drainage pathways by the tumor, leading to increased intracranial pressure (ICP) or causing focal brain dysfunction. Subtle changes in personality, mentation, and speech may precede these classic signs and symptoms; such changes often occur with supratentorial (cortical) lesions. In young children, the diagnosis of a brain tumor may be delayed because the symptoms are similar to those of more common illnesses, such as gastrointestinal disorders, with associated vomiting. Infants with open cranial sutures may present with signs of increased ICP, such as vomiting, lethargy, and irritability, as well as the later finding of macrocephaly. The classic triad of headache, nausea, and vomiting as well as papilledema is associated with midline or infratentorial tumors. Disorders of equilibrium, gait, and coordination occur with infratentorial tumors. Torticollis may occur in cases of cerebellar tonsill herniation. Blurred vision, diplopia, and nystagmus also are associated with infratentorial tumors. Tumors of the brainstem region may be associated with gaze palsy, multiple cranial nerve palsies, and upper motor neuron deficits (e.g., hemiparesis, hyperreflexia, clonus). Supratentorial tumors are more commonly associated with lateralized deficits, such as focal motor weakness, focal sensory changes, language disorders, focal seizures, and reflex asymmetry. Infants with supratentorial tumors may present with premature hand preference. Optic pathway tumors manifest as visual and/or afferent oculomotor disturbances, such as decreased visual acuity, Marcus Gunn pupil (afferent pupillary defect), nystagmus, and/or visual field defects. Suprasellar region tumors and third ventricular region tumors may manifest initially as neuroendocrine deficits, such as subacute development of obesity, abnormal linear growth velocity, diabetes insipidus, galactorrhea, precocious puberty, delayed puberty, and hypothryoidism. In fact, signs of endocrine dysfunction preceded symptoms of neuroophthalmologic dysfunction by an average of 1.9 yr, and their recognition as a possible sign of hypothalamic or pituitary neoplasm can hasten diagnosis and improve outcome. The diencephalic syndrome, which manifests as failure to thrive, emaciation despite normal caloric intake, and inappropriate normal or happy affect, occurs in infants and young children with tumors in these regions. Parinaud syndrome is seen with pineal region tumors and is manifested by paresis of upward gaze, pupillary caliber reactive to accommodation but not to light (pseudopарарол lon pupillary reaction), nystagmus to convergence or retraction, and eyelid retraction. Spinal cord tumors and spinal cord dissemination of brain tumors may manifest as long nerve tract motor and/or sensory

deficits often localized to below a specific spinal level, bowel and bladder deficits, and back or radicular pain. The signs and symptoms of meningeal metastatic disease from brain tumors or leukemia include head or back pain and symptoms referable to compression of cranial nerves or spinal nerve roots.

DIAGNOSIS

The evaluation of a patient in whom a brain tumor is suspected is an emergency. Initial evaluation should include a complete history, physical (including ophthalmic) examination, and neurologic assessment with neuroimaging. For primary brain tumors, MRI with and without gadolinium is the neuroimaging standard. Tumors in the pituitary/suprasellar/optic chiasmal region should undergo evaluation for neuroendocrine dysfunction. Formal ophthalmologic examination is beneficial in patients with optic path region tumors to document the impact of the disease on ocular motor function, visual acuity, and fields of vision. The suprasellar and pineal regions are preferential sites for germ cell tumors (Fig. 497-3). Both serum and CSF measurements of β-human chorionic gonadotropin and α-fetoprotein can assist in the diagnosis of germ cell tumors. In tumors with a propensity for spreading to the leptomeninges, such as medulloblastoma/PNET, ependymoma, and germ cell tumors, lumbar puncture with cytologic analysis of the CSF is indicated; lumbar puncture is contraindicated in individuals with newly diagnosed hydrocephalus secondary to CSF flow obstruction, in tumors that cause supratentorial midline shift, and in individuals with infratentorial tumors. Lumbar puncture in
these individuals may lead to brain herniation, resulting in neurologic compromise and death. Therefore, in children with newly diagnosed intracranial tumors and signs of increased ICP, the lumbar puncture usually is delayed until surgery or shunt placement.

**SPECIFIC TUMORS**

**Astrocytomas**

Astrocytomas are a heterogeneous group of tumors that account for approximately 40% of pediatric CNS malignancies. These tumors occur throughout the CNS.

Low-grade astrocytomas (LGAs), the predominant group of astrocytomas in childhood, are characterized by an indolent clinical course. PA is the most common astrocytoma in children, accounting for approximately 20% of all brain tumors. On the basis of clinicopathologic features using the WHO Classification System, PA is classified as a WHO grade I tumor. Although PA can occur anywhere in the CNS, the classic site is the cerebellum (Fig. 497-4A). Other common sites include the hypothalamic/third ventricular region and the optic nerve and chiasmal region (Fig. 497-4B). The classic but not exclusive neuroradiologic finding in PA is the presence of a contrast medium–enhancing nodule within the wall of a cystic mass (Fig. 497-4A). The microscopic findings include the biphasic appearance of bundles of compact fibrillary tissue interspersed with loose microcystic, spongy areas. The presence of Rosenthal fibers, which are condensed masses of glial filaments occurring in the compact areas, helps establish the diagnosis. PA has a low metastatic potential and is rarely invasive. A

Part XXII  Cancer and Benign Tumors

A small proportion of these tumors can progress and develop leptomeningeal spread, particularly when they occur in the optic path region. A PA very rarely undergoes malignant transformation to a more aggressive tumor. A PA of the optic nerve and chiasmal region is a relatively common finding in patients with neurofibromatosis type 1 (15% incidence). Unlike in diffuse fibrillary astrocytomas, there are no characteristic cytogenetic abnormalities in PA. Other tumors occurring in the pediatric age group with clinicopathologic characteristics similar to those of PA include pleomorphic xanthoastrocytoma, desmoplastic cerebral astrocytoma of infancy, and subependymal giant cell astrocytoma.

The second most common astrocytoma is fibrillary infiltrating astrocytoma, which consists of a group of tumors characterized by a pattern of diffuse infiltration of tumor cells amidst normal neural tissue and potential for anaplastic progression. On the basis of their clinicopathologic characteristics, they are grouped as LGAs (WHO grade II), malignant astrocytomas (anaplastic astrocytoma; WHO grade III), and glioblastoma multiforme (WHO grade IV). Fibrillary LGA accounts for 15% of brain tumors. Histologically, these low-grade tumors demonstrate greater cellularity than normal brain parenchyma, with few mitotic figures, nuclear pleomorphism, and microcysts. The characteristic MRI finding is a lack of enhancement after contrast agent infusion. Molecular genetic abnormalities found among low-grade diffuse infiltrating astrocytomas include mutations of \( \text{P53} \) and overexpression of platelet-derived growth factor \( \alpha \)-chain and platelet-derived growth factor receptor-\( \alpha \). Evolution of fibrillary infiltrating astrocytoma into malignant astrocytoma is associated with cumulative acquisition of multiple molecular abnormalities.

Pilomyxoid astrocytoma occurs most commonly in the hypothalamic/optic chiasmic region and carries a high risk of local as well as cerebrospinal spread. This astrocytoma affects young children and infants. It is classified as a WHO grade II tumor.

The clinical management of LGAs focuses on a multimodal approach incorporating surgery as the primary treatment as well as radiation therapy and chemotherapy. With complete surgical resection the overall survival approaches 80-100%. In patients with partial resection (<80% resection), overall survival varies from 50-95%, depending on the anatomic location of the tumor. In the patient who has undergone partial tumor resection and has stable neurologic status, the current approach is to follow the patient closely by examination and imaging. With evidence of progression, a second surgical resection should be considered. In patients in whom a second procedure was less than complete or is not feasible, radiation therapy is beneficial. Radiation therapy is delivered to the tumor bed at a total cumulative dose ranging from 50-55 Gy given on a daily schedule over 6 wk. Historically, patients with deep midline tumors have been treated empirically with radiation therapy and without surgery or biopsy, with variable survival rates from 33-75%. Modern surgical techniques and innovative radiation therapy methodology, including proton-beam radiation, may have a positive impact on the survival and clinical outcome of these patients. The role of chemotherapy in the management of LGAs is evolving. Because of concerns regarding morbidity from radiation therapy in young children, several chemotherapy approaches have been evaluated, especially in children younger than 10 yr of age. Complete response to chemotherapy is uncommon; however, these approaches have yielded durable control of disease in 70-100% of patients. Patients with midline tumors in the hypothalamic/optic chiasmic region (see Fig. 497-4B) have tended to do less well. Taken together, the chemotherapeutic approaches have permitted delay and, potentially, avoidance of radiation therapy. Chemotherapy agents given singly or in combination for LGA include carboplatin, vincristine, lomustine, procarbazine, temozolomide, and vinblastine. Observation is the primary approach in clinical management of selected patients with LGAs that are biologically indolent. One such group includes patients with neurofibromatosis type 1, in whom an LGA of the optic chiasm/optic pathway or brainstem may be found incidentally. Another group includes patients with midbrain astrocytoma who have resolution of clinical symptoms after ventricular shunting and do not require further intervention. Astrocytomas associated with tuberous sclerosis have responded to everolimus, a mammalian target of rapamycin inhibitor.

Malignant astrocytomas are much less common in children and adolescents than in adults, accounting for 7-10% of all childhood tumors. Among this group, anaplastic astrocytoma (WHO grade III,
and area of necrotic cyst formation. Often depends on the anatomic location of the tumor. MRI demonstrates calcified cortical mass.

Observation of a calcified cortical mass on CT in a patient presenting with a seizure is suggestive of oligodendroglioma. Treatment approaches are similar to those for infiltrating astrocytomas.

**Ependymal Tumors**

Ependymal tumors are derived from the ependymal lining of the ventricular system. Ependymoma (WHO grade II) is the most common of these neoplasms, occurring predominantly in childhood and accounting for 10% of childhood tumors. Approximately 70% of ependymomas in childhood occur in the posterior fossa. The mean age of patients is 6 yr, with approximately 40% of cases occurring in children younger than 4 yr of age. The incidence of leptomeningeal spread approaches 10% overall. Clinical presentation can be insidious and often depends on the anatomic location of the tumor. MRI demonstrates a well-circumscribed tumor with variable and complex patterns of gadolinium enhancement, with or without cystic structures (Fig. 497-6). These tumors usually are noninvasive, extending into the ventricular lumen and/or displacing normal structures, sometimes leading to significant obstructive hydrocephalus. Histologic characteristics include perivascular pseudorosettes, ependymal rosettes, monomorphic nuclear morphology, and occasional nonpalisading foci of necrosis. Other histologic subtypes include anaplastic ependymoma (WHO grade III), which is much less common in childhood and is characterized by a high mitotic index and histologic features of microvascular proliferation and pseudopalisading necrosis. Myxopapillary ependymoma (WHO grade I) is a slow-growing tumor arising from the filum terminale and conus medullaris and appears to be biologically different. There are no well-defined characteristic cytogenetic or molecular genetic alterations in ependymoma, largely owing to their heterogeneous nature, although association of various genotypes with susceptibility to ependymoma have been implicated. Preliminary studies suggest that there are genetically distinct subtypes of ependymoma, exemplified by an association between alterations in the NF2 gene and spinal ependymoma. Surgery is the primary treatment modality, with extent of surgical resection a major prognostic factor. Two other major prognostic factors are age, with younger children having poorer outcomes, and tumor location, with localization in the posterior fossa, which often is seen in young children, associated with poorer outcomes. Surgery alone is rarely curative. Multimodal therapy incorporating irradiation with surgery has resulted in long-term survival in approximately 40% of patients with ependymoma undergoing gross total resection. Recurrence is predominantly local. Ependymoma is sensitive to a spectrum of chemotherapeutic agents; the role of chemotherapy in multimodal therapy of ependymoma is still unclear. Current investigations are directed toward identification of optimal radiation dose, surgical questions addressing the use of second-look procedures after chemotherapy, and further evaluation of classic as well as novel chemotherapeutic agents.

**Choroid Plexus Tumors**

Choroid plexus tumors account for 2-4% of childhood CNS tumors. They are the most common CNS tumor in children younger than 1 yr of age and account for 10-20% of CNS tumors in infants. These tumors are intraventricular epithelial neoplasms arising from the choroid plexus. Children present with signs and symptoms of increased ICP.
Infants may present with macrocephaly and focal neurologic deficits. In children, these tumors predominantly occur supratentorially in the lateral ventricles. Choroid plexus papilloma (WHO grade I), the most common of this group, is a well-circumscribed lesion on neuroimaging and closely resembles normal choroid plexus histologically. Choroid plexus carcinoma (WHO grade III) is a malignant tumor with metastatic potential to seed into the CSF pathways. This malignancy has the following histologic characteristics: nuclear pleomorphism, high mitotic index, and increased cell density. Immunopositivity for transthyretin (prealbumin) is useful in confirming the diagnosis of choroid plexus tumors. These tumors are associated with the Li-Fraumeni syndrome. Simian virus 40 may also play an etiologic role in choroid plexus tumors. After complete surgical resection, the frequency of cure for choroid plexus papilloma approaches 100%, whereas the frequency of cure for choroid plexus carcinoma approaches 20-40%. Reports suggest that radiation therapy and/or chemotherapy may lead to better disease control for choroid plexus carcinoma.

Embryonal Tumors

Embryonal tumors or PNETs are the most common group of malignant CNS tumors of childhood, accounting for approximately 20% of pediatric CNS tumors. They have the potential to metastasize to the neuraxis and beyond. The group includes medulloblastoma, supratentorial PNET, ependymoblastoma, medulloepithelioblastoma, and atypical teratoid/rhabdoid tumor, all of which are histologically classified as WHO grade IV tumors.

Medulloblastoma, which accounts for 90% of embryonal CNS tumors, is a cerebellar tumor occurring predominantly in males and at a median age of 5-7 yr. Most of these tumors occur in the midline cerebellar vermis; however, older patients may present with tumors in the cerebellar hemisphere. CT and MRI demonstrate a solid, homogeneous, contrast medium–enhancing mass in the posterior fossa causing fourth ventricular obstruction and hydrocephalus (Fig. 497-7). Up to 30% of patients with medulloblastoma present with neuroimaging evidence of leptomeningeal spread. Among a variety of diverse histologic patterns of this tumor, the most common is a monomorphic sheet of undifferentiated cells classically noted as small, blue, round cells. Neuronal differentiation is more common among these tumors and is characterized histologically by the presence of Homer Wright rosettes and by immunopositivity for synaptophysin. An anaplastic variant is often more aggressive and may be associated with worse prognosis.

Patients present with signs and symptoms of increased ICP (i.e., headache, nausea, vomiting, mental status changes, and hypertension) and cerebellar dysfunction (i.e., ataxia, poor balance, dysmetria). Standard clinical staging evaluation includes MRI of the brain and spine, both preoperatively and postoperatively, as well as as lumbar puncture after the increased ICP has resolved. The Chang staging system, originally based on surgical information, has been modified to incorporate information from neuroimaging to identify risk categories. Clinical features that have consistently demonstrated prognostic significance include age at diagnosis, extent of disease, and extent of surgical resection. Patients younger than 4 yr of age have a poor outcome, partly as the result of a higher incidence of disseminated disease on presentation and past therapeutic approaches that have used less intense therapies. Patients with disseminated disease at diagnosis (M>0), including positive CSF cytologic result alone (M1), have a markedly worse outcome than those patients with no dissemination (M0). Similarly, patients with gross residual disease after surgery have worse outcomes than those in whom surgery achieved gross total resection of disease.

Cytogenetic and molecular genetic studies have demonstrated multiple abnormalities in medulloblastoma. The most common abnormality involves chromosome 17p deletions, which occur in 30-40% of all cases. These deletions are not associated with P53 mutations. Several signaling pathways have been shown to be active in medulloblastomas, including the sonic hedgehog (SHH) pathway, predominately associated with the desmoplastic variants, and the WNT pathway, which can occur in up to 15% of cases and has been associated with improved survival. Integrative genomic studies have recently identified at least 4 distinct molecular subgroups of medulloblastoma—WNT, SHH, group 3, and group 4—which exhibit highly discriminate transcriptional, cytogenetic, and mutational spectra, in addition to divergent patient demographics and clinical behavior. These prognostic groups still must be validated in larger prospective studies. With the evolution of gene array technology, preliminary studies have identified clusters of genes/gene expression that appear to be associated with metastatic medulloblastoma and outcome.

A multimodal treatment approach is pursued in medulloblastoma, with surgery as the starting point of treatment. Medulloblastoma is sensitive to both chemotherapy and radiation therapy. With technology advances in neurosurgery, neuroradiology, and radiation therapy, as well as identification of chemotherapy as an effective modality, the overall outcome among all patients approaches 60-70%. Standard
Supratentorial primitive neuroectodermal tumors (SPNETs) account for 2-3% of childhood brain tumors, primarily in children within the 1st decade of life. These tumors are similar histologically to medulloblastoma and are composed of undifferentiated or poorly differentiated neuroepithelial cells. Historically, patients with SPNETs have had poorer outcomes than those with medulloblastoma after combined-modality therapy. In current clinical trials, children with SPNETs are considered among the high-risk group and receive dose-intensive chemotherapy with craniospinal radiation therapy.

Atypical teratoid/rhabdoid tumor is a very aggressive embryonal malignancy that occurs predominantly in children younger than 5 yr of age and can occur at any location in the neuraxis. The histology demonstrates a heterogeneous pattern of cells, including rhabdoid cells that express epithelial membrane antigen and neurofilament antigen. The characteristic cytogenetic pattern is partial or complete deletion of chromosome 22q11.2 that is associated with mutation in the INI1 gene. The relation between this mutation and tumorigenesis is unclear. Outcome after combined-modality therapy with intensive chemotherapy is very poor and there is no standard chemotherapy. However, long-term survival is reported for some children, primarily with complete resection and focal radiotherapy.

Pineal Parenchymal Tumors
The pineal parenchymal tumors are the most common malignancies after germ cell tumors that occur in the pineal region. These include pineoblastoma, occurring predominantly in childhood, pineocytoma, and the mixed pineal parenchymal tumors. The therapeutic approach in this group of diseases is multimodal. There was significant concern regarding the location of these masses and the potential complications of surgical intervention. With developments in neurosurgical technique and surgical technology, the morbidity and mortality associated with these approaches have markedly decreased. Stereotactic biopsy of these tumors may be adequate to establish diagnosis; however, consideration should be given to total resection of the lesion before institution of additional therapy. Pineoblastoma, the more malignant variant, is considered a subgroup of childhood PNETs. Chemotherapy regimens incorporate cisplatin, cyclophosphamide (Cytoxan), etoposide (VP-16), and vincristine and/or lomustine. Data have shown that survival outcome of combined chemotherapy and radiation therapy in pineal-region PNETs approaches 70% at 5 yr, similar to that noted for medulloblastoma. Pineocytoma usually is approached with surgical resection.

Craniopharyngioma
Craniopharyngioma (WHO grade I) is a common tumor of childhood, accounting for 7-10% of all childhood tumors. The adamantinomatous variant of craniopharyngioma predominates in childhood. Children with craniopharyngioma often present with endocrinologic abnormalities such as growth failure and delayed sexual maturation. Visual changes can occur and may include decreased acuity or visual field abnormalities. These tumors are often quite large and heterogeneous, displaying both solid and cystic components, and occur within the suprasellar region. They are minimally invasive, adhere to...
Germ Cell Tumors

Germ cell tumors of the CNS are a heterogeneous group of tumors that are primarily tumors of childhood, arising predominantly in midline structures of the pineal and suprasellar regions (see Fig. 497-3). They account for 3-5% of pediatric brain tumors. The peak incidence of these tumors is in children 10-12 yr of age. Overall, there is a male preponderance, although there is a female preponderance for suprasellar tumors. Germ cell tumors occur multifocally in 5-10% of cases. This group of tumors is much more prevalent in Asian populations than European populations. Delays in diagnosis can occur because these tumors have a particularly insidious course; the initial presenting symptoms may be subtle, including poor school performance and behavior problems. As in peripheral germ cell tumors, the analysis of protein markers, $\alpha$-fetoprotein, and $\beta$-human chorionic gonadotropin may be useful in establishing the diagnosis and monitoring treatment response. Surgical biopsy is recommended to establish the diagnosis; however, nongerminomatous germ cell tumors may be diagnosed on the basis of protein marker elevations. Therapeutic approaches to germinomas and mixed germ cell tumors are different. The survival proportion among patients with pure germinoma exceeds 90%. The postsurgical treatment of pure germinomas is somewhat controversial in defining the relative roles of chemotherapy and radiation therapy. Clinical trials have investigated the use of chemotherapy and reduced-dose radiation after surgery in pure germinomas. The therapeutic approach to nongerminomatous germ cell tumors is more aggressive, combining more intense chemotherapy regimens with craniospinal radiation therapy. Survival rates among patients with these tumors are markedly lower than those noted in patients with germinoma, ranging from 40-70% at 5 yr. Trials have shown the benefit of the use of high doses of chemotherapy with peripheral blood stem cell rescue.

Tumors of the Brainstem

Tumors of the brainstem are a heterogeneous group of tumors that account for 10-15% of childhood primary CNS tumors. Outcome depends on tumor location, imaging characteristics, and the patient’s clinical status. Patients with these tumors may present with motor weakness, cranial nerve dysfunction, cerebellar dysfunction, and/or signs of increased ICP. On the basis of MRI evaluation and clinical findings, tumors of the brainstem can be classified into 4 types: focal (5-10% of patients); dorsally exophytic (5-10%); cervicesmedullary (5-10%); and diffuse intrinsic (70-85%) (Fig. 497-8). Surgical resection is the primary treatment approach for focal and dorsally exophytic tumors and leads to a favorable outcome.Histologically, these 2 groups usually are low-grade gliomas. Cervicesmedullary tumors, owing to their location, may not be amenable to surgical resection but are sensitive to radiation therapy. Diffuse intrinsic tumors, characterized by the diffuse infiltrating pontine glioma, are associated with a very poor outcome independent of histologic diagnosis. These tumors are not amenable to surgical resection. Biopsy in children in whom MRI shows a diffuse intrinsic tumor is controversial and is not recommended unless there is suspicion of another diagnosis, such as infection, vascular malformation, multiple sclerosis or other disorder of myelination, or metastatic tumor. These diagnoses are much more common in adults. The standard approach for treatment of diffuse infiltrating pontine gliomas has been radiation therapy, and median survival with this treatment is 12 mo, at best. Use of chemotherapy, including high-dose chemotherapy with peripheral blood stem cell rescue, has not yet been of survival benefit in this group of patients. Current approaches include evaluation of investigational agents alone or in combination with radiation therapy, similar to approaches being pursued in patients with malignant gliomas.

Metastatic Tumors

Metastatic spread of other childhood malignancies to the brain is uncommon. Childhood acute lymphoblastic leukemia and non-Hodgkin lymphoma can spread to the leptomeninges, causing symptoms of communicating hydrocephalus. Chloromas, which are collections of myeloid leukemia cells, can occur throughout the neuraxis. Rarely, brain parenchymal metastases occur from lymphoma, neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, osteosarcoma, and clear cell sarcoma of the kidney. Therapeutic approaches are based on the specific histologic diagnosis and may incorporate radiation therapy, intrathecal administration of chemotherapy, and/or systemic administration of chemotherapy. Medulloblastoma is the childhood brain tumor that most commonly metastasizes extraneurally. Less commonly, extraneural metastases from malignant glioma, PNET, and ependymoma can occur. Ventriculoperitoneal shunts have been known to allow extraneural metastases, primarily within the peritoneal cavity but also systemically.

COMPLICATIONS AND LONG-TERM MANAGEMENT

Data from the National Cancer Institute Surveillance, Epidemiology and End Results Program indicate that more than 70% of patients with childhood brain tumors will be long-term survivors. At least 50% of these survivors will experience chronic problems as a direct result of their tumors and treatment. These problems include chronic neurologic deficits such as focal motor and sensory abnormalities, seizure disorders, neurocognitive deficits (e.g., developmental delays, learning disabilities), and neuroendocrine deficiencies (e.g., hypothyroidism, growth failure, delay or absence of puberty). These patients are also at significant risk for secondary malignancies. Supportive multidisciplinary interventions for children with brain tumors both during and after therapy may help improve the ultimate outcome. Optimal seizure management, physical therapy, endocrine management with timely growth hormone and thyroid replacement therapy, tailored educational programs, and vocational interventions may enhance the childhood brain tumor survivor’s quality of life.

Bibliography is available at Expert Consult.
Bibliography

Neuroblastomas are embryonal cancers of the peripheral sympathetic nervous system with heterogeneous clinical presentation and course, ranging from tumors that undergo spontaneous regression to very aggressive tumors unresponsive to very intensive multimodal therapy. The causes of most cases remain unknown, and although significant advances have been made in the treatment of children with these tumors, the outcomes for aggressive forms of neuroblastoma remain poor.

**EPIDEMIOLOGY**

Neuroblastoma is the most common extracranial solid tumor in children and the most commonly diagnosed malignancy in infants. Approximately 600 new cases are diagnosed each year in the United States, accounting for 8-10% of childhood malignancies and one third of cancers in infants. Neuroblastoma accounts for >15% of the mortality from cancer in children. The median age of children at diagnosis of neuroblastoma is 22 mo, and 90% of cases are diagnosed by 5 yr of age. The incidence is slightly higher in boys and in whites.

**PATHOLOGY**

Neuroblastoma tumors, which are derived from primordial neural crest cells, form a spectrum with variable degrees of neural differentiation, ranging from tumors with primarily undifferentiated small round cell neuroblastoma (tumors consisting of mature and maturing Schwannian stroma with ganglion cells (ganglioneuroblastoma or ganglioneuroma). The tumors may resemble other small round blue cell tumors, such as rhabdomyosarcoma, Ewing sarcoma, and non-Hodgkin lymphoma. The prognosis of children with neuroblastoma varies with the histologic features of the tumor, and prognostic factors include the presence and amount of Schwannian stroma, the degree of tumor cell differentiation, and the mitosis-karyorrhexis index.

**PATHOGENESIS**

The etiology of neuroblastoma in most cases remains unknown. Familial neuroblastoma accounts for 1-2% of all cases, is associated with a younger age at diagnosis, and is linked to mutations in the PHOX2B and ALK genes. The BARD1 gene has also been identified as a major genetic contributor to neuroblastoma risk. Neuroblastoma is associated with other neural crest disorders, including Hirschsprung disease, central hypoventilation syndrome, and neurofibromatosis type I, and potentially congenital cardiovascular malformations (Table 498-1). Children with Beckwith-Wiedemann syndrome and hemihypertrophy also have a higher incidence of neuroblastoma. Increased incidence of neuroblastoma is associated with some maternal and paternal occupational chemical exposures, farming, and work related to electronics, although no single environmental exposure has been shown to directly cause neuroblastoma.

Genetic characteristics of neuroblastoma tumors that are of prognostic importance include amplification of the MYCN (N-myc) proto-oncogene and tumor cell DNA content, or ploidy (Tables 498-2 to 498-4). Amplification of MYCN is strongly associated with advanced tumor stage and poor outcomes. Hyperdiploidy confers better prognosis if the child is younger than 1 yr of age at diagnosis. Other chromosomal abnormalities, including loss of heterozygosity of 1p, 11q, and 14q, and gain of 17q, are commonly found in neuroblastoma tumors and are also associated with worse outcomes. In addition, many other biologic factors are associated with neuroblastoma outcomes, including tumor vascularity and the expression levels of nerve growth factor receptors (TrkA, TrkB), ferritin, lactate dehydrogenase, ganglioside GD2, neuropeptide Y, chromogranin A, CD44, multidrug resistance–associated protein, and telomerase. These factors and many others are under investigation in clinical trials to determine whether they can be used to reduce therapy for children predicted to fare well with minimal therapy and to intensify therapy for those predicted to be at high risk for relapse.

**CLINICAL MANIFESTATIONS**

Neuroblastoma may develop at any site of sympathetic nervous system tissue. Approximately half of neuroblastoma tumors arise in the adrenal glands, and most of the remainder originate in the paraspinal sympathetic ganglia. Metastatic spread, which is more common in children older than 1 yr of age at diagnosis, occurs via local invasion or distant hematogenous or lymphatic routes. The most common sites of metastasis are the regional or distant lymph nodes, long bones and skull, bone marrow, liver, and skin. Lung and brain metastases are rare, occurring in >3% of cases.

The signs and symptoms of neuroblastoma reflect the tumor site and extent of disease, and the symptoms of neuroblastoma can mimic many other disorders, a fact that can result in a delayed diagnosis. Metastatic disease can cause a variety of signs and symptoms, including fever, irritability, failure to thrive, bone pain, cytopenias, bluish subcutaneous nodules, orbital proptosis, and periorbital ecchymoses (Fig. 498-1). Localized disease can manifest as an asymptomatic mass or can cause rapid-onset obesity, hypothalamic dysfunction, hypoventilation, autonomic dysregulation.

symptoms because of the mass itself, including spinal cord compression, bowel obstruction, and superior vena cava syndrome.

Children with neuroblastoma can also present with neurologic signs and symptoms. Neuroblastoma originating in the superior cervical ganglion can result in Horner syndrome. Paraspinal neuroblastoma tumors can invade the neural foramina, causing spinal cord and nerve root compression. Neuroblastoma can also be associated with a paraneoplastic syndrome of autoimmune origin, termed opsoclonus-myoclonus-ataxia syndrome, in which patients experience rapid, uncontrollable jerking eye and body movements, poor coordination,
and cognitive dysfunction. Some tumors produce catecholamines that can cause increased sweating and hypertension, and some release vasoactive intestinal peptide, causing a profound secretory diarrhea. Children with extensive tumors can also experience tumor lysis syndrome and disseminated intravascular coagulation. Infants younger than 1 yr of age also can present in unique fashion, termed stage 4S, with widespread subcutaneous tumor nodules, massive liver involvement, limited bone marrow disease, and a small primary tumor without bone involvement or other metastases.

**DIAGNOSIS**

Neuroblastoma is usually discovered as a mass or multiple masses on plain radiography, CT, or MRI (Fig. 498-2A). The mass often contains calcification and hemorrhage that can be appreciated on plain radiography or CT. Prenatal diagnosis of neuroblastoma on maternal ultrasound scans is sometimes possible. Tumor markers, including catecholamine metabolites homovanillic acid and vanillylmandelic acid, are elevated in the urine of approximately 95% of cases and help to confirm the diagnosis. A pathologic diagnosis is established from tissue obtained by biopsy. Neuroblastoma can be diagnosed without a primary tumor biopsy if small round blue tumor cells are observed in bone marrow samples (Fig. 498-3) and the levels of vanillylmandelic acid or homovanillic acid are elevated in the urine.

Evaluations for metastatic disease should include CT or MRI of the chest and abdomen, bone scans to detect cortical bone involvement, and at least 2 independent bone marrow aspirations and biopsies to evaluate for marrow disease. Iodine-123 metaiodobenzylguanidine (123I-MIBG) studies should be used when available to better define the extent of disease (see Fig. 498-2B and C). MRI of the spine should be performed in cases with suspected or potential spinal cord compression, but imaging of the brain with either CT or MRI is not routinely performed unless dictated by the clinical presentation.

The International Neuroblastoma Staging System (INSS) is currently used to stage patients with neuroblastoma after initial surgical resection (see Table 498-3). INSS stage 1 tumors are confined to the organ or structure of origin and are completely resected. INSS stage 2 tumors extend beyond the structure of origin but not across the midline, either with (stage 2B) or without (stage 2A) ipsilateral lymph node involvement. INSS stage 3 tumors extend beyond the midline, with or without bilateral lymph node involvement, whereas INSS stage 4 tumors are disseminated, with metastases to bones, bone marrow, liver, distant lymph nodes, and other organs. INSS stage 4S refers to neuroblastoma in children younger than 1 yr of age with dissemination to liver, skin, and/or bone marrow without bone involvement and with a primary tumor that would otherwise be staged as INSS stage 1 or 2. A new International Neuroblastoma Risk Group Staging System was recently developed to allow for more effective comparisons of treatments and outcomes worldwide.

**TREATMENT**

Treatment strategies for neuroblastoma have changed dramatically over the past 20 yr, with significant reduction in treatment intensity for children who have localized low-risk tumors and with continued increased treatment intensity and addition of new agents for treatment of children who have high-risk neuroblastoma. The patient’s age and tumor stage are combined with cytogenetic and molecular features of the tumor to determine the treatment risk group and estimated prognosis for each patient (see Tables 498-2 to 498-4). The usual treatment for children with low-risk neuroblastoma is surgery for stages 1 and 2 and observation for stage 4S with cure rates generally >90% without further therapy. Treatment with chemotherapy or radiation for the rare child with local recurrence can still be curative. Children with spinal cord compression at diagnosis also may require urgent treatment with chemotherapy, surgery, or radiation to avoid neurologic

*Patients are assigned to prognostic groups according to risk, as described by the Children’s Oncology Group, with the level of risk defining the likelihood of death from disease. Stage 4S disease is considered separately here because of the unique phenotype of favorable biologic features and relentless early progression but ultimately full and complete regression of the disease.

†The goal of surgery is to safely debulk the tumor mass and avoid damage to surrounding normal structures while also obtaining sufficient material for molecular diagnostic studies. Some localized tumors may spontaneously regress without surgery.

‡Low-dose chemotherapy or radiation therapy, or both, is used in patients with life-threatening hepatic involvement, especially in infants <2 mo of age, who are at much higher risk for life-threatening complications from massive hepatomegaly.

Induction chemotherapy for children with high-risk neuroblastoma includes combinations of cyclophosphamide, topotecan, doxorubicin, vincristine, cisplatin, and etoposide. After completion of induction chemotherapy, resection of the residual primary tumor is followed by high-dose chemotherapy with autologous stem cell rescue and focal radiation therapy to tumor sites. A national cooperative group trial demonstrated significantly better survival with chemotherapy plus autologous stem cell rescue than with chemotherapy alone. The further addition of 13-cis-retinoic acid after autologous stem cell transplantation resulted in further improvements in survival rates. In addition, a national clinical trial has demonstrated an increase in short-term survival rates with the addition of the monoclonal antibody ch14.18, interleukin 2, and granulocyte-macrophage colony-stimulating factor to 13-cis-retinoic acid therapy.

Cases of high-risk neuroblastoma are associated with frequent relapses, and children with recurrent neuroblastoma have a <50% response rate to alternative chemotherapy regimens. New treatment strategies and agents are needed for children with both high-risk and recurrent neuroblastoma. Therapies currently under investigation include new chemotherapeutic agents and other novel therapies directed against critical intracellular signaling pathways, radiolabeled targeted agents (such as $^{131}$I-MIBG), immunotherapy, and antitumor vaccines. Ongoing biologic studies of neuroblastoma will also hopefully lead to the identification of new molecular and genetic targets for therapy.

Chapter 498  Neuroblastoma  2464.e1

Bibliography

Wilms tumor (WT), also known as nephroblastoma, is the most common primary malignant renal tumor of childhood; other renal tumors are very rare. It is the second most common malignant
abdominal tumor in childhood. The most common sites of metastases are the lungs, regional lymph nodes, and liver. Histologically, the classic WT is made up of varying proportions of blastemal, stromal, and epithelial cells, recapitulating stages of normal renal development. The treatment includes surgery and chemotherapy with or without radiotherapy. The use of multimodality treatment and multinstitutional cooperative group trials has dramatically improved the cure rate of WT from <30% to approximately 90% (Table 499-1).

**ETIOLOGY: GENETICS AND MOLECULAR BIOLOGY**

WT is thought to be derived from incompletely differentiated renal mesenchyme, and tumors are typically composed of cells reminiscent of the undifferentiated and partially differentiated cells that normally arise from renal mesenchyme. Foci of benign, undifferentiated mesenchyme (nephrogenic rests) that persist abnormally in the kidney into postnatal life are observed in approximately 1% of children in the general population, but are present in up to 90% of children who have a family history of WT, develop bilateral tumors, or display features of WT-related syndromes. Nephrogenic rests usually regress or differentiate, but those that persist can become malignant.

To date genetic mutations have been detected, either individually or in combination, in a third of WTs. Mutations in WT1, a gene located at 11p13 and encoding a zinc finger transcription factor, are observed in 15-20% of tumors. These are homozygous and result in loss of WT1 function. The majority of WT1 mutations are somatic, result in loss of WT1 function, and are present homозygously. However, germline WT1 mutations are also observed, primarily in patients with WT-associated syndromes, or sometimes in patients with bilateral disease. In these instances, the wild-type allele present in the germline is mutated or lost in the tumor, resulting in loss of WT1 function. Interestingly, nephrogenic rests assessed from patients heterozygous for a germline WT1 mutation are homozygous for the WT1 mutation, with additional somatic mutations being observed in the autologous tumors. The vast majority of WT1 mutations are deletion/truncating mutations or missense mutations that affect amino acid residues critical for WT1 function. Germline truncating mutations are usually associated with WT in the context of genitourinary anomalies or the WAGR (Wilms, aniridia, genitourinary anomalies, mental retardation) syndrome. Missense germline mutations are usually observed in children with Denys-Drash syndrome in which early-onset renal failure is observed.

Mutations in CTNNB1, encoding β-catenin, which acts as a major regulatory point in the wnt signaling pathway and also acts at the cytoplasmic membrane, are observed in approximately 15% of WTs, very often those that have sustained WT1 mutations. WTX, a gene located on the X chromosome that encodes a protein that also plays a role in wnt pathway regulation, is mutated in approximately 20% of tumors. CTNNB1 and WTX mutations are somatic. Somatic mutation of the p53 gene, TP53, is observed in approximately 5% of tumors and is associated with anaplastic tumor histology, a poor prognostic feature of WT.

In approximately 70% of tumors, loss of heterozygosity (usually copy number neutral) or loss of imprinting at imprinted loci at 11p15 is observed. This epigenetic alteration (the observation of which led to the designation of a “WT2” gene) occurs in tumors both with and without WT1, CTNNB1, or WTX mutations, and often results in biallelic expression of IGF2, a normally imprinted gene that encodes insulin-like growth factor 2, in addition to the loss of imprinting of other 11p15 genes. Families with Beckwith-Wiedemann syndrome, a somatic overgrowth syndrome in which predisposition to embryonal tumors (including WT) is observed, have been genetically linked to 11p15, and microdeletions within the IGF2 imprinting control region are present in Beckwith-Wiedemann syndrome families in which WT is observed.

WT is occasionally observed in families with a predisposition to pleuropulmonary blastoma, and mutations in the DICER1 gene, located at 14q31 and encoding a key protein in the generation of microRNAs, are observed in these families. However, outside the context of these families, DICER1 mutations are rare in WTs.

A family history of WT is noted in approximately 2% of WT patients, and predisposition is inherited as an autosomal dominant trait with incomplete penetrance. Predisposition to other tumor types or other phenotypes are not observed in the vast majority of these families. WT1 mutations are detected in <3% of families, and these WT1-related families are small, with only 2 affected individuals. Genetic linkage analyses of large WT families have localized predisposition genes to 19q and 17q, but neither gene has been identified yet. However, none

**EPIEDEMOLOGY**

WT accounts for 6% of pediatric malignancies and more than 95% of kidney tumors in children. In the United States, the incidence of WT is approximately 8 cases per 1 million children younger than 15 yr of age per year, and about 650 new cases are diagnosed each year. Approximately 75% of the cases occur in children younger than 5 yr with a peak incidence at 2-3 yr of age. It can arise in 1 or both kidneys; the incidence of bilateral WTs is 7%. Most cases are sporadic, but approximately 2% of patients have a family history. In 8-10% of patients, WT is observed in the context of hemihypertrophy, aniridia, genitourinary anomalies, and a variety of rare syndromes, including Beckwith-Wiedemann syndrome and Denys-Drash syndrome (Table 499-2). An earlier age of diagnosis and an increased incidence of bilateral disease are generally observed in syndromic and familial cases.
families carry neither of these mutations, suggesting that additional WT loci exist. Some families are not linked to either of these genomic regions, indicating that additional WT predisposition genes exist. Similarly, somatic alterations at 1q, 7p, 16q, chromosome 12, and other genomic regions are observed in some WTs and are thought to harbor genes important in WT development.

**CLINICAL PRESENTATION**
The most common initial clinical presentation for WT is the incidental discovery of an asymptomatic abdominal mass by parents while bathing or clothing an affected child or by a physician during a routine physical examination (Table 499-3). At presentation the mass can be quite large because retroperitoneal masses can grow unhampered by strict anatomic boundaries. Functional defects in paired organs like the kidney, with good functional reserve, are unlikely to be detected early. Hypertension is present in approximately 25% of tumors at presentation and has been attributed to increased renin activity. Abdominal pain, gross painless hematuria, and fever are other frequent findings at diagnosis. Occasionally, rapid abdominal enlargement and anemia occur as a result of bleeding into the renal parenchyma or pelvis. WT thrombus extends into the inferior vena cava in 4-10% of patients, and rarely into the right atrium. Patients might also have microcytic anemia from iron deficiency or anemia of chronic disease, polycythemia, elevated platelet count, and acquired deficiency of von Willebrand factor or factor VII deficiency.

**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS**
An abdominal mass in a child should be considered malignant until diagnostic imaging, laboratory findings, and pathology can define its true nature (see Table 499-3). Imaging studies include plain abdominal radiography, abdominal ultrasonography, and CT of the abdomen to define the intrarenal origin of the mass and differentiate it from adrenal masses (e.g., neuroblastoma) and other masses in the abdomen. Abdominal ultrasonography helps differentiate solid from cystic masses. WT might show focal areas of necrosis or hemorrhage and hydrenephrosis caused by obstruction of the renal pelvis by the tumor. Ultrasonography with Doppler imaging of renal veins and the inferior vena cava is a useful first study that not only can look for WT but also can evaluate the collecting system and demonstrate tumor thrombi in the renal veins and inferior vena cava.

CT (Fig. 499-1) is useful to define the extent of the disease, integrity of the contralateral kidney, and metastasis. MRI requires sedation in young children and is not routinely used; it may be helpful in defining an extensive tumor thrombus that extends up to the level of the hepatic veins or even into the right atrium, and to distinguish WT from nephrogenic rests. Chest CT is more sensitive than chest radiography to screen for pulmonary metastasis, and is preferably performed before surgery because effusions and atelectasis can confound the interpretation of postoperative imaging studies. A bone scan is performed if the histologic diagnosis confirms clear cell sarcoma of the kidney to look for bone metastasis. Brain imaging with CT or MRI is obtained in cases of clear cell sarcoma of the kidney or rhabdoid tumor of the kidney as these tumors can spread to the brain.

WT lesions are metabolically active and concentrate fluorodeoxyglucose. Regional spread and metastatic lesions can be visualized on positron emission tomography/CT scanning. The diagnosis is usually made by imaging studies and confirmed by histology at the time of nephrectomy. Although biopsy is a reliable diagnostic tool, it is discouraged as it results in disease upstaging. A core needle biopsy obtained via a posterior approach should be performed in cases of unusual imaging findings (significant adenopathy, no renal parenchyma seen, intratumoral calcification).

**TREATMENT**
There are 2 major schools of thought in the management of WT. The Children's Oncology Group, formerly National Wilms Tumor Study Group, advocates upfront surgery prior to initiating treatment. On the

Other hand, the International Society of Pediatric Oncology recommends preoperative chemotherapy. Each approach has advantages and limitations but they have similar outcomes. Early surgery provides accurate diagnosis and staging, and can facilitate risk-adapted therapy. Preoperative chemotherapy can make surgery easier and reduces the risk of intraoperative tumor rupture and hemorrhage. Surgery entails a radical nephrectomy with meticulous dissection to avoid rupture of the tumor capsule and lymph node sampling despite the absence of abnormal nodes on preoperative imaging studies or intraoperative assessment. Partial nephrectomy is performed in patients with bilateral disease or with unilateral WT and a predisposing syndrome such as Denys-Drash and WAGR, so as to minimize the risk of future renal failure.

Prognostic factors for risk-adapted therapy include age, stage, tumor weight, and loss of heterozygosity at chromosomes 1p and 16q (Table 499-4). Histology plays a major role in risk stratification of WT. Absence of anaplasia is considered a favorable histologic finding. Presence of anaplasia is further classified as focal or diffuse, both of which are unfavorable histologic findings.

The Children’s Oncology Group has specific drug dose and schedule recommendations for risk-adapted therapy of WT. Patients with favorable histology who achieve complete response to therapy have a good outcome and are generally treated in the outpatient setting. Nephrectomy alone may be sufficient for patients younger than 2 yr of age with stage I disease and a tumor weighing <550 g. Patients with stages I and II disease receive chemotherapy with 2 drugs, vincristine and actinomycin D (also called dactinomycin), every 1-3 wk for a total of 18 wk (regimen EE4A). Patients with stage III or IV disease receive chemotherapy with 3 drugs (vincristine, doxorubicin, and actinomycin D) every 1-3 wk for a total of 24 wk (regimen DD4A) and radiation therapy. Patients with regional lymph node metastases, residual disease after surgery, or tumor rupture receive radiation therapy to the flank or abdomen, and those with lung metastases receive radiation therapy to the lungs. The presence of loss of heterozygosity at 1p and 16q confers an adverse prognosis, and deserves treatment intensification.

Anaplastic histology (focal and diffuse) accounts for approximately 11% of WT cases. Patients with diffuse anaplasia, in particular, have a poor outcome. They are treated with intensive chemotherapy regimens that include vincristine, cyclophosphamide, doxorubicin, etoposide, carboplatin, and ifosfamide, in addition to radiation therapy.

#### RECURRENT DISEASE

Approximately 15% of WT patients with favorable histology and 50% of those with anaplastic histology suffer relapse; most relapses occur early (within 2 yr of diagnosis). Factors associated with a favorable outcome after relapse include low stage (I/II) at diagnosis, treatment with vincristine and actinomycin D only, no prior radiotherapy, favorable histology, relapse to lung only, and interval from nephrectomy to relapse 12 mo or longer. Patients with recurrent WT who previously received only vincristine and actinomycin D had a 4 yr survival of approximately 80%, whereas those who previously received the 3 drug regimen of vincristine, actinomycin D, and doxorubicin had a 4 yr survival of only 50%. Other agents used to treat recurrent WT include doxorubicin, carboplatin, cyclophosphamide, ifosfamide, etoposide, and topotecan. Metachronous WT may not represent tumor relapse but instead may indicate development of a new tumor in the opposite kidney.

#### PROGNOSIS

Despite some adverse risk factors that decrease prognosis (metastases, unfavorable histology, recurrent disease, and loss of heterozygosity of both 1p and 16q), most children with WT have a very favorable prognosis. Overall, the survival of children with WT approaches 90%, with some prognostic factors (low stage, favorable histology, young age, low tumor weight) conferring even better outcomes.

#### LATE EFFECTS

Current strategies are successful with relatively few long-term effects of therapy. Late complications are a consequence of treatment type and intensity; the use of radiotherapy and anthracyclines increases the risk of these complications. Clinically significant late sequelae include musculoskeletal effects, cardiac toxicity, pulmonary disease, reproductive problems, renal dysfunction, and the development of second malignant neoplasms.

### 499.2 Other Pediatric Renal Tumors

#### MESOBLASTIC NEPHROMA

Mesoblastic nephroma is the most common solid renal tumor identified in the neonatal period and the most frequent benign renal tumor in childhood. It represents 3-10% of all pediatric renal tumors. Many cases are diagnosed with prenatal ultrasound and can manifest as polyhydramnios, hydrops, and premature delivery. Most of the patients are diagnosed before 3 mo of age, whereas WT is rarely diagnosed before 6 mo of age. Radical nephrectomy is the treatment of choice and may be sufficient by itself. Local recurrence is uncommon. Although rare, malignant variants do occur, marked by metastases to the lung, liver, heart, and brain.

#### CLEAR CELL SARCOMA OF THE KIDNEY

Clear cell sarcoma of the kidney is an uncommon renal neoplasm of childhood with approximately 20 new cases diagnosed each year in North America. Peak incidence is between 1 and 4 yr of age, usually presenting as an abdominal mass. Gene expression profiles of clear cell sarcoma of the kidney suggest the cell of origin to be a renal mesenchymal cell with neural markers. Bone is the most common site of distant metastasis followed by lung, abdomen, retroperitoneum, brain, and liver. Therefore, the staging work-up should include a bone scan. Early-stage disease has an excellent prognosis, especially with the addition of doxorubicin.

#### RHABDOID TUMOR OF THE KIDNEY

Malignant rhabdoid tumor of the kidney has rhabdomyoblast-like morphology. It is a rare but aggressive cancer. Hematuria is a common presenting feature. Both rhabdoid tumor of the kidney and central nervous system atypical teratoid rhabdoid tumors have deletions and mutations of the hSNF5/INI1 gene and are considered to be related. Prognosis is poor with current therapeutic protocols. The 5 yr overall survival rate is <30%.
RENAL CELL CARCINOMA
Renal cell carcinoma (RCC) is rare in children, accounting for <5% of all renal tumors of childhood. Patients may present with frank hematuria, flank pain, and/or a palpable mass, although RCC can be asymptomatic and detected incidentally. It has a propensity to metastasize to the lungs, bone, liver, and brain. RCC can be associated with von Hippel-Lindau disease. Unlike the case for adult RCC, local lymph node involvement is not a poor prognostic indicator in pediatric RCC. Nephrectomy alone may be adequate for early-stage RCC.

Bibliography is available at Expert Consult.
Bibliography
The annual incidence of soft tissue sarcomas is 8.4 cases per 1 million white children younger than 14 yr of age. Rhabdomyosarcoma accounts for more than 50% of soft tissue sarcomas. The prognosis most strongly correlates with age and extent of disease at diagnosis, primary tumor site and histology, and expression of the fusion protein, PAX-FOXO1.

**Rhabdomyosarcoma**

**Epidemiology**

The most common pediatric soft tissue sarcoma, rhabdomyosarcoma, accounts for approximately 3.5% of childhood cancers. These tumors may occur at virtually any anatomic site but are usually found in the head and neck (25%), orbit (9%), genitourinary tract (24%), and extremities (19%); retroperitoneal and other sites account for the remainder of primary sites. The incidence at each anatomic site is related to both patient age and tumor type. Extremity lesions are more likely to occur in older children and to have alveolar histology. Rhabdomyosarcoma occurs with increased frequency in patients with neurofibromatosis and other family cancer predisposition syndromes such as Li-Fraumeni syndrome.

**Pathogenesis**

Rhabdomyosarcoma is thought to arise from the same embryonic mesenchyme as striated skeletal muscle although a large percentage of these tumors arise in areas lacking skeletal muscle (e.g., bladder, prostate, vagina). On the basis of light microscopic appearance, it belongs to the general category of small round cell tumors that includes Ewing sarcoma, neuroblastoma, and non-Hodgkin lymphoma. Definitive diagnosis of a pathologic specimen requires immunohistochemical studies using antibodies to skeletal muscle (desmin, muscle-specific actin, myogenin) and reverse transcription polymerase chain reaction or, in the case of alveolar tumors, fluorescent in situ hybridization for PAX-FOXO1 transcript.

Determination of the specific histologic subtype is important in treatment planning and assessment of prognosis. There are 3 recognized histologic subtypes. The **embryonal type** accounts for approximately 60% of all cases and has an intermediate prognosis. The **botryoid type**, a variant of the embryonal form in which tumor cells and an edematous stroma project into a body cavity like a bunch of grapes, is found most often in the vagina, uterus, bladder, nasopharynx, and middle ear. The **alveolar type** accounts for approximately 25-40% of cases and often is characterized by the presence of PAX-FOXO1 fusion transcript. The tumor cells tend to grow in nests that often have cleft-like spaces resembling alveoli. Alveolar tumors occur most often in the trunk and extremities and carry the poorest prognosis. The **pleomorphic type** (adult form) is rare in childhood, accounting for <1% of cases.

**Clinical Manifestations**

The most common presenting feature of rhabdomyosarcoma is a mass that may or may not be painful. Symptoms are caused by displacement or obstruction of normal structures (Table 500-1). Origin in the nasopharynx may be associated with nasal congestion, mouth breathing, epistaxis, and difficulty with swallowing and chewing. Regional extension into the cranium can produce cranial nerve paralysis, blindness, and signs of increased intracranial pressure with headache and vomiting. When the tumor develops in the face or cheek, there may be swelling, pain, and trismus, and, as extension occurs, paralysis of cranial nerves. Tumors in the neck can produce progressive swelling with neurologic symptoms after regional extension. Orbital primary tumors are usually diagnosed early in their course because of associated ptosis, proptosis, periorbital edema, ptosis, change in visual acuity, and local pain. When the tumor arises in the middle ear, the most common early signs are pain, hearing loss, chronic otorrhea, or a mass in the ear canal; extensions of tumor produce cranial nerve paralysis and signs of an intracranial mass on the involved side. An unremitting croupy cough and progressive stridor can accompany rhabdomyosarcoma of the larynx. Because most of these signs and symptoms also are associated with common childhood conditions, clinicians must be alert to the possibility of tumor.

Rhabdomyosarcoma of the trunk or extremities often is first noticed after trauma and initially may be regarded as a hematoma. If the swelling does not resolve or increases, malignancy should be suspected. Involvement of the genitourinary tract can produce hematuria, obstruction of the lower urinary tract, recurrent urinary tract infections, incontinence, or a mass detectable on abdominal or rectal examination. Paratesticular tumor usually manifests as a painless, rapidly growing mass in the scrotum. Vaginal rhabdomyosarcoma may manifest as a grape-like mass of tumor tissue bulging through the vaginal orifice, known as **sarcoma botryoides**, and can cause urinary tract or large bowel symptoms. Vaginal bleeding or obstruction of the urethra or rectum may occur. Similar findings can be noted with uterine primaries.

T1, confined to anatomic site of origin; T2, extension and/or fixative to surrounding tissue.

Size: a, <5 cm in diameter; b, ≥5 cm in diameter.

Nodes: N0, regional nodes not involved; N1, regional nodes involved; Nx, regional node status unknown.

Metastases: M0, no distant metastases; M1, metastases present (includes positive cytology in CSF, pleural, or peritoneal fluid).
Tumors in any location may disseminate early and cause symptoms of pain or respiratory distress associated with pulmonary metastases. Extensive bone involvement can produce symptomatic hypercalcemia. In such cases, it may be difficult to identify the primary lesion.

**Diagnosis**

Early diagnosis of rhabdomyosarcoma requires a high index of suspicion. The microscopic appearance is that of a small, round, blue cell tumor. Neuroblastoma, lymphoma, and Ewing sarcoma also are small, round, blue cell tumors from which suspected rhabdomyosarcomas must be differentiated. The differential diagnosis depends on the site of presentation. Definitive diagnosis is established by biopsy, microscopic appearance, and results of immunohistochemical stains and analysis of PAX/FOXO1 expression. A lesion in an extremity may be thought to be a hematoma or hemangioma; an orbital lesion resulting in proptosis may be treated as an orbital cellulitis; or bladder-obstructive symptoms may be missed. Adolescents may ignore or be embarrassed to mention paratesticular lesions for a long time. Unfortunately, several months often elapse between the initial symptoms and biopsy. Diagnostic procedures are determined mainly by the area of involvement. CT or MRI is necessary for evaluation of the primary tumor site. With signs and symptoms in the head and neck area, radiographs should be examined for evidence of a tumor mass and for indications of bony erosion. MRI should be performed to identify intracranial extension or meningeal involvement and also to reveal bony involvement or erosion at the base of the skull. For abdominal and pelvic tumors, CT with a contrast agent or MRI can help delineate the tumor (Fig. 500-1). A radionuclide bone scan, chest CT, and bilateral bone marrow aspiration and biopsy should be performed to evaluate the patient for the presence of metastatic disease and to plan treatment. Fluorodeoxyglucose positron emission tomography is being used more frequently to enhance staging. The most critical element of the diagnostic work-up is examination of tumor tissue, which includes the use of special histochecmal stains and immunostains. Molecular genetics is important to detect fusion transcripts present in alveolar rhabdomyosarcoma (PAX-FOX1). Lymph nodes also should be sampled for the presence of disease spread, especially in tumors of the extremities and in boys older than 10 yr of age with paratesticular tumors.

**Treatment**

Treatment is multidisciplinary and includes the pediatric oncologist, pediatric surgeon or other surgical subspecialist, and most often radiation oncologist. Only if the tumor is able to be completely resected, with negative margins, without loss of function or major cosmetic deformity should this be attempted initially. Unfortunately, most rhabdomyosarcomas are not completely resectable at initial diagnosis. Treatment is based on risk classification of the tumor, which is determined by the stage of tumor, the tumor histology, and the amount of tumor that was surgically resected prior to chemotherapy (‘surgical group’). Stage is dependent on primary site (favorable vs unfavorable), tumor invasiveness (T1 or T2), lymph node status, tumor size, and presence of metastasis. Favorable sites include female genital, paratesticular, and head and neck (nonparameningeal) regions; all other sites are considered unfavorable. Table 500-1 shows the Children’s Oncology Group staging system for rhabdomyosarcoma. Patients should be offered enrollment in clinical trials. Table 500-2 shows current risk stratification and outcome based on results of recent studies. Patients with low-risk disease can be cured with minimal therapy consisting of vincristine and of actinomycin with or without lower doses of cyclophosphamide; radiation therapy can be used in the case of residual disease after initial surgery. Treatment for patients with intermediate-risk disease consists of vincristine, actinomycin, and cyclophosphamide along with radiation. Clinical trials in North America are available at the Children’s Oncology Group website (www.cure.org).

<table>
<thead>
<tr>
<th>TISSUE TYPE</th>
<th>TUMOR</th>
<th>NATURAL HISTORY AND BIOLOGY</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adipose</td>
<td>Liposarcoma</td>
<td>A very rare tumor. Usually arises in the extremities or retroperitoneum; associated with a nonrandom translocation, t(12;16)(q13;p11). Tends to be locally invasive and rarely metastasizes; wide local excision is the treatment of choice. The role of radiation therapy and chemotherapy in treating gross residual or metastatic disease is not established.</td>
</tr>
<tr>
<td>Fibrous</td>
<td>Fibrosarcoma</td>
<td>Most common soft tissue sarcoma in children younger than 1 yr. Congenital fibrosarcoma is a low-grade malignancy that commonly arises in the extremities or trunk and rarely metastasizes. Surgical excision is treatment of choice; dramatic responses to preoperative chemotherapy may occur. In children older than 4 yr, the natural history is similar to that in adults (a 5 yr survival rate of 60%); wide surgical excision and preoperative chemotherapy are commonly used. Associated with t(12;15)(p13;q25) or trisomy 11, also +8, +17, +20.</td>
</tr>
<tr>
<td>Malignant fibrous histiocytoma</td>
<td>Most commonly arises in the trunk and extremities, deep in the subcutaneous layer. Histologically subdivided into storiform, giant cell, myxoid, and angiomatoid variants. The angiomatoid type tends to affect younger patients and is curable with surgical resection alone. Wide surgical excision is the treatment of choice. Chemotherapy has produced objective tumor regressions.</td>
<td></td>
</tr>
<tr>
<td>Vascular</td>
<td>Hemangiopericytoma</td>
<td>Often arises in the lower extremities or retroperitoneum; may manifest as hypoglycemia and hypophosphatemic rickets. Both benign and malignant histology. Nonrandom translocations t(12;19)(q13;p13) and t(13;22)(q22;q13.3) have been described. Complete surgical excision is the treatment of choice. Chemotherapy and radiation therapy may produce responses.</td>
</tr>
<tr>
<td>Angiosarcoma</td>
<td></td>
<td>Rare in children; 33% arise in skin, 25% in soft tissue, and 25% in liver, breast, or bone. Associated with chronic lymphedema and exposure to vinyl chloride in adults. Survival rate is poor (12% at 5 yr) despite some responses to chemotherapy/radiation therapy. Can occur in soft tissue, liver, and lung. Localized lesions have a favorable outcome; lesions in lung and liver often are multifocal and have a poor prognosis.</td>
</tr>
<tr>
<td>Hemangioendothelioma</td>
<td></td>
<td>Complete surgical excision is necessary for survival; response to chemotherapy is suboptimal.</td>
</tr>
<tr>
<td>Peripheral nerves</td>
<td>Neurofibrosarcoma</td>
<td>Also known as the malignant peripheral nerve sheath tumor. Develops in up to 16% of patients with neurofibromatosis type 1 (NF1); almost 50% occur in patients with NF1. Deletions of chromosome 22q11-q13 or 17q11 and p53 mutations have been reported. Commonly arises in trunk and extremities and is usually locally invasive. Complete surgical excision is necessary for survival; response to chemotherapy is suboptimal.</td>
</tr>
<tr>
<td>Synovium</td>
<td>Synovial sarcoma</td>
<td>The most common nonrhabdomyosarcoma soft tissue sarcoma in some series. Often manifesting in the 3rd decade, but 33% of patients are younger than age 20 yr. Typically arises around the knee or thigh and is characterized by a nonrandom translocation t(X;18)(p11;q11). Wide surgical excision is necessary. Radiation therapy is effective in microscopic residual disease, and ifosfamide-based therapy is active in advanced disease.</td>
</tr>
<tr>
<td>Unknown</td>
<td>Alveolar soft part sarcoma</td>
<td>Slow-growing tumor; tends to recur or to metastasize to lung and brain years after diagnosis. Often arises in the extremities and head and neck.</td>
</tr>
<tr>
<td>Smooth muscle</td>
<td>Leiomyosarcoma</td>
<td>Often arises in the gastrointestinal tract and may be associated with a t(12;14)(q14;q23) translocation. Associated with Epstein-Barr virus in immunodeficiency syndromes (including AIDS). Complete surgical excision is the treatment of choice.</td>
</tr>
</tbody>
</table>

---

America are investigating the role of topoisomerase inhibitors in this group of patients. For patients with high-risk disease, newer approaches using intensive multiagent chemotherapy along with biologic agents are being investigated.

**Prognosis**

Prognostic factors include age, stage, histology, and primary site. Among patients with resectable tumor and favorable histology, 80-90% have prolonged disease-free survival. Unresectable tumor localized to certain favorable sites, such as the orbit, also has a high likelihood of cure. Approximately 65-70% of patients with incompletely resected tumor also achieve long-term disease-free survival. Patients with disseminated disease have a poor prognosis; only approximately 50% achieve remission, and fewer than 50% of these are cured. Older children have a poorer prognosis than younger children. For all patients, surveillance for late effects of cancer treatment is extremely important. Some examples of late effects include infertility from cyclophosphamide, late effects in the radiation field such as bladder dysfunction, infertility, cataracts, impaired bone growth, and secondary malignancies. (Table 500-3). Because they are relatively rare in children, much of the information about their natural history and treatment has been derived from studies in adult patients. In children, the median age at diagnosis is 12 yr, with a male:female ratio of 2.3:1. These tumors commonly arise in the trunk or lower extremities. The most common histologic types are synovial sarcoma (42%), fibrosarcoma (13%), malignant fibrous histiocytoma (12%), and neurogenic tumors (10%). Molecular genetic studies often prove useful in diagnosis, because several of these tumors have characteristic chromosomal translocations. Tumor size, stage (clinical group), invasiveness, and histologic grade correlate with survival.

Surgery remains the mainstay of therapy, but a careful search for lung and bone metastases should be undertaken before surgical excision. Chemotherapy and radiation therapy should be considered for large, high-grade, and unresectable tumors. The role of chemotherapy for nonrhabdomyosarcoma soft tissue sarcomas is not as well defined as for rhabdomyosarcoma. Patients with unresectable or metastatic disease are treated with multiagent chemotherapy in addition to irradiation and/or surgery. Patients with completely resected small (<5 cm) tumors are generally treated with surgery alone and can be expected to have an excellent outcome regardless of whether the tumor is high or low grade.

Bibliography is available at Expert Consult.
Bibliography

501.1 Malignant Tumors of Bone  
Carola A.S. Arndt  

The annual incidence of malignant bone tumors in the United States is approximately 7 cases per 1 million white children younger than 14 yr of age, with a slightly lower incidence in African-American children. Osteosarcoma is the most common primary malignant bone tumor in children and adolescents, followed by Ewing sarcoma (Table 501-1; Fig. 501-1). In children younger than 10 yr of age, Ewing sarcoma is more common than osteosarcoma. Both tumor types are most likely to occur in the second decade of life.

**OSTEOSARCOMA**

**Epidemiology**

The annual incidence of osteosarcoma in the United States is 5.6 cases per 1 million children younger than 15 yr of age. The highest risk period for development of osteosarcoma is during the adolescent growth spurt, suggesting an association between rapid bone growth and malignant transformation. Patients with osteosarcoma are taller than their peers of similar age.

**Pathogenesis**

Although the cause of osteosarcoma is unknown, certain genetic or acquired conditions predispose patients to development of osteosarcoma. Patients with hereditary retinoblastoma have a significantly increased risk for development of osteosarcoma. The sites of osteosarcoma in these patients were initially thought to be only in previously irradiated areas, but later studies show them to arise in sites far from the original retinoblastoma radiation field. Predisposition to development of osteosarcoma in these patients may be related to loss of heterozygosity of the RB gene. Osteosarcoma also occurs in the Li-Fraumeni syndrome, which is a familial cancer syndrome associated with germline mutations of the P53 gene. Kindreds with

figure 501-1 A, Age and skeletal distribution of 1,649 cases of osteosarcoma in the Mayo Clinic files. B, Age and skeletal distribution of 512 cases of Ewing sarcoma in the Mayo Clinic files. (From Unni KK, editor: Dahlin’s bone tumors: general aspects and data on 11,087 cases, ed 5, Philadelphia, 1996, Lippincott-Raven. Reprinted by permission of the Mayo Foundation.)
Li-Fraumeni syndrome have a spectrum of malignancies in 1st-degree relatives, including carcinoma of the breast, soft tissue sarcomas, brain tumors, leukemia, adrenal cortical carcinoma, and other malignancies. Rothmund-Thomson syndrome is a rare syndrome associated with short stature, skin telangiectasia, small hands and feet, hypoplasticity or absence of the thumbs, and a high risk of osteosarcoma. Osteosarcoma also can be induced by irradiation for Ewing sarcoma, craniospinal irradiation for brain tumors, or high-dose irradiation for other malignancies. Other benign conditions that can be associated with malignant transformation to osteosarcoma include Paget disease, enchondromatosis, multiple hereditary exostoses, and fibrous dysplasia.

The pathologic diagnosis of osteosarcoma is made by demonstration of a highly malignant, pleomorphic, spindle cell neoplasm associated with the formation of malignant osteoid and bone. There are 4 pathologic subtypes of conventional high-grade osteosarcoma: osteoblastic, fibroblastic, chondroblastic, and telangiectatic. No significant differences in outcome are associated with the various subtypes, although the chondroblastic component of that subtype may not respond as well to chemotherapy. The role in prognosis of various genes such as drug resistance–related genes, tumor-suppressor genes, and genes related to apoptosis is being evaluated.

Telangiectatic osteosarcoma may be confused with aneurysmal bone cyst because of its lytic appearance on radiography. High-grade osteosarcoma typically arises in the diaphyseal region of long bones and invades the medullary cavity. It also may be associated with a soft tissue mass. Two variants of osteosarcoma, parosteal and periosteal osteosarcoma, should be distinguished from conventional osteosarcoma because of their characteristic clinical features. Parosteal osteosarcoma is a low-grade, well-differentiated tumor that does not invade the medullary cavity and most commonly is found in the posterior aspect of the distal femur. Surgical resection alone is curative in this lesion, which has a low propensity for metastatic spread. Periosteal osteosarcoma is a rare variant that arises on the surface of the bone but has a higher rate of metastatic spread than the parosteal type and an intermediate prognosis.

Clinical Manifestations
Pain, limp, and swelling are the most common presenting manifestations of osteosarcoma. Because these tumors occur most often in active adolescents, initial complaints may be attributed to a sports injury or sprain; any bone or joint pain not responding to conservative therapy within a reasonable time should be investigated thoroughly. Additional clinical findings may include limitation of motion, joint effusion, tenderness, and warmth. Results of routine laboratory tests, such as a complete blood cell count and chemistry panel, are usually normal, although alkaline phosphatase or lactate dehydrogenase values may be elevated.

Diagnosis
Bone tumor should be suspected in a patient who presents with deep bone pain, often causing nighttime awakening, in whom there is a palpable mass and radiographs that demonstrate a lesion. The lesion may be mixed lytic and blastic in appearance, but new bone formation is usually visible. The classic radiographic appearance of osteosarcoma is the sunburst pattern (Fig. 501-2). When osteosarcoma is suspected, the patient should be referred to a center with experience in managing bone tumors. The biopsy and the surgery should be performed by the same surgeon so that the incisional biopsy site can be placed in a manner that will not compromise the ultimate limb salvage procedure. Tissue usually is obtained for molecular and biologic studies at the time of the initial biopsy. Before biopsy, MRI of the primary lesion and the entire bone should be performed to evaluate the tumor for its proximity to nerves and blood vessels, soft tissue and joint extension, and skip lesions. The metastatic work-up, which should be performed before biopsy, includes CT of the chest and radionuclide bone scanning to evaluate for lung and bone metastases, respectively. The differential diagnosis of a lytic bone lesion includes histiocytosis, Ewing sarcoma, lymphoma, and bone cyst.

Figure 501-2 Radiograph of an osteosarcoma of the femur with typical “sunburst” appearance of bone formation.

Treatment
With chemotherapy and surgery, the 5-yr disease-free survival rate of patients with nonmetastatic extremity osteosarcoma is 65-75%. Complete surgical resection of the tumor is important for cure. The current approach is to treat patients with preoperative chemotherapy in an attempt to facilitate limb salvage operations and to treat micrometastatic disease immediately. Up to 80% of patients are able to undergo limb salvage operations after initial chemotherapy. It is important to resume chemotherapy as soon as possible after surgery. Lung metastases present at diagnosis should be resected by thoracotomies at some time during the course of treatment. Active agents currently in use in multidrug chemotherapy regimens for conventional osteosarcoma include doxorubicin, cisplatin, methotrexate, and ifosfamide.

One of the most important prognostic factors in osteosarcoma is the histologic response to chemotherapy. An international cooperative group is performing a randomized trial of the postoperative addition of high-dose ifosfamide with etoposide to standard 3 drug therapy with cisplatin, doxorubicin, and methotrexate to improve the outcome of patients with a poor histologic response. Patients with a good histologic response were randomized to the addition of pegylated interferon-α2b. Results are anticipated in the near future. For patients with metastatic disease, a new approach is the addition of zoledronic acid, a bisphosphonate, to intensive chemotherapy, with results pending. After limb salvage surgery, intensive rehabilitation and physical therapy are necessary to ensure maximal functional outcome.

For patients who require amputation, early prosthetic fitting and gait training are essential to enable patients to resume normal activities as soon as possible. Before definitive surgery, patients with tumors on weight-bearing bones should be instructed to use crutches to avoid stressing the weakened bones and causing pathologic fracture. The role of chemotherapy in parosteal and periosteal osteosarcomas is not well defined, and chemotherapy is generally reserved for use in patients with tumors which have a high-grade microscopic appearance.
Prognosis
Surgical resection alone is curative only for patients with parosteal osteosarcoma. Conventional osteosarcoma requires multagent chemotherapy. Up to 75% of patients with nonmetastatic extremity osteosarcoma are cured with current multagent treatment protocols. The prognosis is not as favorable for patients with pelvic tumors as for those with primary tumors in the extremities. Twenty percent to 30% of patients who have limited numbers of pulmonary metastases also can be cured with aggressive chemotherapy and resection of lung nodules. Patients with bone metastases and those with widespread lung metastases have an extremely poor prognosis. Long-term follow-up of patients with osteosarcoma is important to monitor for late effects of chemotherapy, such as cardiotoxicity from anthracycline and hearing loss from cisplatin. Patients in whom late, isolated lung metastases develop may be cured with surgical resection of the metastatic lesions alone.

EWING SARCOMA
Epidemiology
The incidence of Ewing sarcoma in the United States is 2.1 cases per 1 million children. It is rare among African-American children. Ewing sarcoma, an undifferentiated sarcoma of bone, also may arise from soft tissue. The term Ewing sarcoma family of tumors refers to a group of small, round cell, undifferentiated tumors thought to be of neural crest origin that generally carry the same chromosomal translocation. This family of tumors includes Ewing sarcoma of bone and soft tissue and peripheral primitive neuroectodermal tumor. Treatment protocols for these tumors are the same whether the tumors arise in bone or soft tissue. Anatomic sites of primary tumors arising in bone are distributed evenly between the extremities and the central axis (pelvis, spine, and chest wall). Primary tumors arising in the chest wall are often referred to as Askin tumors.

Pathogenesis
Immunohistochemical staining assists in the diagnosis of Ewing sarcoma to differentiate it from small, round, blue cell tumors such as lymphoma, rhabdomyosarcoma, and neuroblastoma. Histochemical stains may react positively with certain neural markers on tumor cells (neuron-specific enolase and S-100), especially in peripheral primitive neuroectodermal tumors. Reactivity with muscle markers (e.g., desmin, actin) is absent. Additionally, MIC-2 (CD99) staining is usually positive. A specific chromosomal translocation, t(11;22), or a variant thereof is found in most of the Ewing sarcoma family of tumors. Analysis for the translocation by FISH (fluorescent in situ hybridization) or polymerase chain reaction analysis for the chimeric fusion gene products EWS/FLI1 or EWS/ERG is utilized routinely in diagnosis.

Clinical Manifestations
Symptoms of Ewing sarcoma are similar to those of osteosarcoma. Pain, swelling, limitation of motion, and tenderness over the involved bone or soft tissue are common presenting symptoms. Patients with huge chest wall primary tumors may present with respiratory distress. Patients with paraspinal or vertebral primary tumors may present with symptoms of cord compression. Ewing sarcoma often is associated with systemic manifestations, such as fever and weight loss; patients may have undergone treatment for a presumptive diagnosis of osteomyelitis or a fever of unknown origin. Patients also may have a delay in diagnosis when their pain or swelling is attributed to a sports injury.

Diagnosis
The diagnosis of Ewing sarcoma should be suspected in a patient who presents with pain and swelling, with or without systemic symptoms, and with a radiographic appearance of a primarily lytic bone lesion with periosteal reaction, the characteristic onion-skinning (Fig. 501-3). A large, associated, soft tissue mass often is visualized on MRI or CT (Fig. 501-4). The differential diagnosis includes osteosarcoma, osteomyelitis, Langerhans cell histiocytosis, primary lymphoma of bone, metastatic neuroblastoma, or rhabdomyosarcoma in the case of a pure soft tissue lesion. Patients should be referred to a center with
experience in managing bone tumors for evaluation and biopsy. Thorough evaluation for metastatic disease includes CT of the chest, radio-nuclide bone scan, and bone marrow aspiration and biopsy specimens from at least 2 sites. MRI of the tumor and the entire length of involved bone should be performed to determine the exact extension of the soft tissue and bony mass and the proximity of tumor to neurovascular structures. Fluorodeoxyglucose positron emission tomography scanning is being incorporated to enhance staging. Studies are also using fluorodeoxyglucose positron emission tomography to evaluate response to therapy.

To avoid compromising an ultimate potential for limb salvage by a poorly planned biopsy incision, the same surgeon should perform the biopsy and the surgical procedure. CT-guided biopsy of the lesion often provides diagnostic tissue. It is important to obtain adequate tissue for special stains and molecular studies.

**Treatment**

Tumors of the Ewing sarcoma family are best managed with a comprehensive multidisciplinary approach in which the surgeon, chemotherapist, and radiation oncologist plan therapy. Multiagent chemotherapy is important because it can shrink the tumor rapidly and is usually given before local control is attempted. In North America, standard chemotherapy for nonmetastatic Ewing sarcoma includes vincristine, doxorubicin, cyclophosphamide, etoposide, and ifosfamide. Chemotherapy usually causes dramatic shrinkage of the soft tissue mass and rapid, significant pain relief. The most recent published randomized study for patients with nonmetastatic Ewing sarcoma showed a statistically significantly better outcome when patients were treated on a 14-day schedule than on a 21-day schedule. Current studies are evaluating the addition of topoisomerase inhibitors to standard chemotherapy, and plans are under way to investigate the role of insulin-like growth factor receptor inhibitors for certain groups of patients. An international cooperative group trial is evaluating whether myeloablative chemotherapy and stem cell rescue is superior to chemotherapy with lung irradiation for patients with pulmonary metastases. Ewing sarcoma is considered a radiosensitive tumor, and local control may be achieved with irradiation or surgery. Radiation therapy is associated with a risk of radiation-induced second malignancies, especially osteosarcoma, as well as failure of bone growth in skeletally immature patients. Many centers prefer surgical resection, if possible, to achieve local control. It is important to provide the patient with crutches if the tumor is in a weight-bearing bone, to avoid a pathologic fracture before definitive local control. Chemotherapy should be resumed as soon as possible after surgery.

**Prognosis**

Patients with small, nonmetastatic, distally located extremity tumors have the best prognosis, with a cure rate of up to 75%. Patients with pelvic tumors have, until recently, had a much worse outcome. Patients with metastatic disease at diagnosis, especially bone or bone marrow metastases, have a poor prognosis, with <30% surviving long term. New approaches, such as very intensive chemotherapy with peripheral blood stem cell rescue, are being investigated in these patients.

Long-term follow-up of patients with Ewing sarcoma is important because of the potential for late effects of treatment, such as anthracycline cardiotoxicity; second malignancies, especially in the radiation field; and late relapses, even as long as 10 yr after initial diagnosis.

**501.2 Benign Tumors and Tumor-Like Processes of Bone**

*Carola A.S. Arndt*

Benign bone lesions in children are common in comparison with the relatively rare malignant neoplasms of bone. They present diagnostic challenges. Some, although histologically benign, can be life-threatening. No single element in the history or diagnostic test is sufficient to rule out malignancies or suggest the existence of non-neoplastic conditions. A broad range of diagnostic possibilities must be considered when the physician is confronted with an undiagnosed bone lesion. Benign lesions may be painless or painful, especially if a pathologic fracture is impending. Night pain that awakens a child suggests malignancy, but relief of such pain with aspirin is common with benign lesions such as osteoid osteomas. Rapidly enlarging lesions usually are associated with malignancy, but several benign lesions, such as aneurysmal bone cysts, can enlarge faster than most malignancies. Several conditions, such as osteomyelitis, can simulate the appearance of benign bone tumors.

Many benign bone tumors are diagnosed incidentally or after pathologic fracture. Management of these fractures is similar to that of nonpathologic fractures in the same location. It is unusual for benign bone tumors to interfere with fracture healing. Likewise, the fractures rarely result in changes or healing of these tumors, which usually are treated after the fracture has healed.

Radiographs of any suspected bone lesion should always be obtained in 2 planes. Additional studies may be necessary to help arrive at the correct diagnosis and to guide treatment. Although these lesions are benign, many do require intervention.

**Osteochondroma (exostosis)** is one of the most common benign bone tumors in children. Because many are completely asymptomatic and unrecognized, the true incidence of this lesion is unknown. Most osteochondromas develop in childhood, arising from the metaphysis of a long bone, particularly the distal femur, proximal humerus, and proximal tibia. The lesion enlarges with the child until skeletal maturity. Most are discovered at 3–15 yr of age, when the child or parent notices a bony, nonpainful mass. Some are discovered because they are irritated by pressure during athletic or other activities. Osteochondromas appear radiographically as stalks or broad-based projections from the surface of the bone, usually in a direction away from the adjacent joint. Invariably, the lesion is radiographically smaller than suggested by palpation because the cartilage cap covering the lesion is not seen. This cartilage cap may be up to 1 cm thick. Both the cortex of the bone and the marrow space of the involved bone are continuous with the lesion. Malignant degeneration of a chondrosarcoma is rare in children but occurs in as many as 1% of adults. Routine removal is not performed unless the lesion is large enough to cause symptoms or grows rapidly.

**Multiple hereditary exostoses** is a related but rare condition characterized by the presence of multiple osteochondromas. Severely involved children can have short stature, limb-length inequality, premature partial physal arrest, and deformity of both the upper and lower extremities. These children must be monitored carefully during growth.

**Enchondroma** is a benign lesion of hyaline cartilage that occurs centrally in the bone. Most of these lesions are asymptomatic and occur in the hands. Most are discovered incidentally, although pathologic fractures often lead to the diagnosis. Radiographically, the lesions occupy the medullary canal, are radiolucent, and are sharply margined. Punctate or stippled calcification may be present within the lesion, but this is much more common in adults than in children. Almost all enchondromas are solitary. Most can simply be observed, with curettage and bone grafting reserved for lesions that are symptomatic or large enough to weaken the bone structurally. Multifocal involvement is referred to as **Ollier disease** and can result in bone dysplasia, short stature, limb-length inequality, and joint deformity. Surgery may be necessary to correct or prevent such deformities. When multiple enchondromas are associated with angiomas of the soft tissue, the condition is referred to as **Maffucci syndrome**. A high rate of malignant transformation has been reported in both of these multifocal conditions.

**Chondroblastoma** is a rare lesion usually found in the epiphysis of long bones. Most patients present in the 2nd decade with complaints of mild to moderate pain in the adjacent joint. Common sites include the hip, shoulder, and knee. Muscle atrophy and local tenderness may be the only clinical findings. The lesion appears radiographically as a sharply margined radiolucency within the epiphysis or apophysis, occasionally with metaphyseal extension across the physis. Proximity to the joint can cause deformity of the subchondral bone, an effusion, or erosion into the joint. Recognition is important because most lesions
can be cured with curettage and bone grafting before joint destruction occurs.

**Chondromyxoid fibroma** is an uncommon benign bone tumor in children. This metaphyseal lesion usually causes pain and local tenderness. The lesion occasionally is asymptomatic. Chondromyxoid fibroma appears radiographically as eccentric, lobular, metaphyseal radiolucency with sharp, sclerotic, and scalloped margins. The lower extremity is involved most often. Treatment usually consists of curettage and bone grafting or en bloc resection.

**Osteoid osteoma** is a small benign bone tumor. Most of these tumors are diagnosed between 5 and 20 yr of age. The clinical pattern is characteristic, consisting of unremitting and gradually increasing pain that often is worst at night and is relieved by aspirin. Boys are affected more often than girls. Any bone can be involved, but the most common sites are the proximal femur and tibia. Vertebral lesions can cause scoliosis or symptoms that mimic a neurologic disorder. Examination can reveal a limp, atrophy, and weakness when the lower extremity is involved. Palpation and range of motion do not alter the discomfort. Radiographs are distinctive, showing a round or oval metaphyseal or diaphyseal lucency (0.5-1.0 cm in diameter) surrounded by sclerotic bone. The central lucency, or nidus, shows intense uptake on bone scan. Approximately 25% of osteoid osteomas are not visualized on plain radiographs but can be identified with CT. Because of the small size of the lesion and its location adjacent to thick cortical bone, MRI is poor at detecting osteoid osteomas. Treatment is directed at removing the lesion. This can involve en bloc excision, curettage, or percutaneous CT-guided ablation of the nidus. Patients with mild pain may be treated with salicylates. Some lesions resolve spontaneously after skeletal maturity.

**Osteoblastoma** is a locally destructive, progressively growing lesion of bone with a predilection for the vertebrae, although almost any bone may be involved. Most patients note the insidious onset of dull aching pain, which may be present for months before patients seek medical attention. Spinal lesions can cause neurologic symptoms or deficits. The radiographic appearance is variable and less distinctive than that of other benign bone tumors. Approximately 25% show features suggesting a malignant neoplasm, making biopsy necessary in many cases. Expansile spinal lesions often involve the posterior elements. Treatment involves curettage and bone grafting or en bloc excision; care must be taken to preserve nerve roots when treating spinal lesions. Surgical stabilization of the spine may be necessary.

**Fibromas (nonossifying fibroma, fibrous cortical defect, metaphyseal fibrous defect)** are fibrous lesions of bone that occur in 40% of children older than 2 yr of age. They most likely represent a defect in ossification rather than a neoplasm and usually are asymptomatic. Most are discovered incidentally when radiographs are taken for other reasons, usually to rule out a fracture after trauma. Occasional pathologic fractures can occur through rare large lesions. Physical examination usually is unrevealing. Radiographs show a sharply marginated eccentric lucency in the metaphyseal cortex. Lesions may be multilocular and expansible, with extension from the cortex into the medullary bone. The long axis of the lesion runs parallel to that of the bone. Approximately 50% are bilateral or multiple. Because of the characteristic radiographic appearance, most lesions do not require biopsy or treatment. Spontaneous regression can be expected after skeletal maturity. Curettage and bone grafting may be recommended for lesions occupying >50% of the bone diameter because of the risk of a pathologic fracture.

**Unicameral bone cysts** can occur at any age in childhood but are rare in children younger than 3 yr of age and after skeletal maturity. The cause of these fluid-filled lesions is unknown. Some resolve spontaneously after skeletal maturity is reached. Most are asymptomatic until diagnosis, which usually follows a pathologic fracture. Such fractures can occur with relatively minor trauma, such as with throwing or catching a ball. Unicameral bone cysts appear radiographically as solitary, centrally located lesions within the medullary portion of the bone. These cysts are most common in the proximal humerus or femur. They often extend to (but not through) the physis and are sharply marginated. The cortex expands, but that does not exceed the width of the adjacent physis. Treatment involves allowing the pathologic fracture to heal, followed by aspiration and injection with methylprednisolone or bone marrow. Repeat injections, curettage, and bone grafting occasionally are necessary to treat recurrent lesions.

**Aneurysmal bone cyst** is a reactive lesion of bone seen in persons younger than 20 yr of age. The lesion is characterized by cavernous spaces filled with blood and solid aggregates of tissue. Although the femur, tibia, and spine are most commonly involved, this progressively growing, expansile lesion develops in any bone. Pain and swelling are common. Spinal involvement can lead to cord or nerve root compression and associated neurologic symptoms, including paralysis. Radiographs show eccentric lytic destruction and expansion of the metaphysis surrounded by a thin sclerotic rim of bone. Posterior elements of the spine are involved more commonly than the vertebral body. Unlike most other benign bone tumors, which usually are confined to a single bone, aneurysmal bone cysts can involve adjacent vertebrae. Rapid growth is characteristic and can lead to confusion with malignant neoplasms. Treatment consists of curettage and bone grafting or excision. Spinal lesions can require stabilization after excision. As with other benign tumors, attempts are made to preserve nerve roots and other vital structures. Recurrence after surgical treatment occurs in 20-30% of patients, is more common in younger than older children, and usually occurs in the 1st 1-2 yr after treatment.

**Fibrous dysplasia** is a developmental abnormality characterized by fibrous replacement of cancellous bone. Lesions may be solitary or multifocal (polyostotic), relatively stable, or progressively more severe. Most children are asymptomatic, although those with skull involvement might have swelling or exophthalmos. Pain and limp are characteristic of proximal femoral involvement. Limb-length discrepancy, bowing of the tibia or femur, and pathologic fractures may be presenting complaints. The triad of polyostotic disease, precocious puberty, and cutaneous pigmentation is known as Albright syndrome. Radiographic features of fibrous dysplasia include a lytic or ground-glass expansile lesion of the metaphysis or diaphysis. The lesion is sharply marginated and often is surrounded by a thick rim of sclerotic bone. Bowing, especially of the proximal femur, may be present. Treatment usually involves observation. Surgery is indicated for patients with progressive deformity, pain, or impending pathologic fractures. Bone grafting is not as successful in the treatment of fibrous dysplasia as with other benign tumors, because the lesion often recurs within the grafted bone. Reconstru ctive surgical techniques often are necessary to provide stability.

**Osteofibrous dysplasia** affects children 1-10 yr of age. This lesion usually involves the tibia. It is clinically, radiographically, and histologically distinct from fibrous dysplasia. Most children present with anterior swelling or enlargement of the leg. Progression is unlikely after 10 yr of age. Radiographs show solitary or multiple lucent cortical diaphyseal lesions surrounded by sclerosis. Anterior bowing of the tibia is often present. The radiographic appearance closely resembles that of adamantinoma, a malignant neoplasm, making biopsy more common than with other benign bone tumors. Treatment involves observation. Some lesions heal spontaneously. Excision and bone grafting should be delayed until the child is older than 10 yr of age because of a high recurrence rate before this age. Pathologic fractures heal with immobilization.

**Langerhans cell histiocytosis** is a monostotic or polyostotic disease that can also involve the skin, liver, or other organs. Single-site disease should be distinguished from the other forms of Langerhans cell histiocytosis (Hand-Schüller-Christian or Letterer-Siwe variants), which can have a less favorable prognosis (see Chapter 507). Langerhans cell histiocytosis usually occurs during the 1st 3 decades of life and is most common in boys 5-10 yr of age. The skull is most commonly affected, but any bone may be involved. Patients usually present with local pain and swelling. Marked tenderness and warmth often are present in the area of the involved bone. Spinal lesions can cause pain, stiffness, and occasional neurologic symptoms. The radiographic appearance of the skeletal lesions is similar in all forms of Langerhans cell histiocytosis but is variable enough to mimic many other benign and malignant lesions of bone. The radiolucent lesions have well-defined or irregular margins with expansion of the involved bone and peristeal new bone formation. Spine involvement can cause uniform compression or flattening of the vertebral body. A skeletal survey is warranted because
polyostotic involvement and the typical skull lesions strongly suggest the diagnosis of eosinophilic granuloma. Biopsy often is necessary to confirm the diagnosis because of the broad radiographic differential diagnosis. Treatment includes curettage and bone grafting, low-dose radiation therapy, or corticosteroid injection. Observation for symptomatic lesions is reasonable because most osseous lesions heal spontaneously and do not recur. Children with bone lesions should be evaluated for visceral involvement because treatment of Hand-Schüller-Christian disease and Letterer-Siwe disease is more complex and often systemic.

Bibliography

Retinoblastoma is an embryonal malignancy of the retina and the most common intraocular tumor in children. Although the survival rate of children in the United States and developed countries with retinoblastoma is extremely high, retinoblastoma progresses to metastatic disease and death in over 50% of children worldwide. Furthermore, the associated loss of vision and side effects of therapy are significant problems that remain to be addressed.

EPIDEMIOLOGY
Approximately 250-350 new cases of retinoblastoma are diagnosed each year in the United States, with no known racial or gender predilection. The cumulative lifetime incidence of retinoblastoma is approximately 1:20,000 live births, and retinoblastoma accounts for 4% of all pediatric malignancies. The median age at diagnosis is approximately 2 yr, and more than 90% of cases are diagnosed in children younger than 5 yr of age. Overall, about 66-75% of children with retinoblastoma have unilateral tumors, with the remainder having bilateral retinoblastoma. Bilateral involvement is more common in younger children, particularly in those diagnosed younger than the age of 1 yr, and is always heritable. There is a possible increased risk of retinoblastoma in children conceived by in vitro fertilization.

Retinoblastoma can be either hereditary or sporadic. Hereditary cases usually are diagnosed at a younger age and are multifocal and bilateral, whereas sporadic cases are usually diagnosed in older children who tend to have unilateral, unifocal involvement. The hereditary form is associated with loss of function of the retinoblastoma gene (RB1) via gene mutation or deletion. The RB1 gene is located on chromosome 13q14 and encodes the retinoblastoma protein, a tumor-suppressor protein that controls cell-cycle phase transition and has roles in apoptosis and cell differentiation. Many different causative mutations have been identified, including translocations, deletions, insertions, point mutations, and epigenetic modifications such as gene methylation. The nature of the predisposing mutation can affect the penetrance and expressivity of retinoblastoma development.

According to Knudson’s “two-hit” model of oncogenesis, 2 mutational events are required for retinoblastoma tumor development (see Chapter 492). In the hereditary form of retinoblastoma, the first mutation in the RB1 gene is inherited through germinatal cells and a second mutation occurs subsequently in somatic retinal cells. Second mutations that lead to retinoblastoma often result in the loss of the normal allele and concomitant loss of heterozygosity. Parents and siblings of a child with a germline mutation should be referred to a genetic specialist for testing; most children with hereditary retinoblastoma have spontaneous new germinal mutations, and both parents have wild-type retinoblastoma genes. All 1st-degree relatives of children with known or suspected hereditary retinoblastoma should have retinal examinations to identify retinomas or retinal scars, which may suggest hereditary retinoblastoma even though malignant retinoblastoma did not develop. In the sporadic form of retinoblastoma, the 2 mutations occur in somatic retinal cells. Heterozygous carriers of oncogenic RB1 mutations demonstrate variable phenotypic expression.

PATHOGENESIS
Histologically, retinoblastoma appears as a small round blue cell tumor with rosette formation (Flexner-Wintersteiner rosettes). It may arise in any of the nucleated layers of the retina and exhibit various degrees of differentiation. Retinoblastoma tumors tend to outgrow their blood supply, resulting in necrosis and calcification.

Endophytic tumors arise from the inner surface of the retina and grow into the vitreous, and can also grow as tumors suspended within the vitreous itself, known as vitreous seeding. Exophytic tumors grow from the outer retinal layer and can cause retinal detachment. Diffuse infiltrating tumors grow inretaretinally and remain flat; these are less common and can cause iris neovascularization. Tumors can also be both endophytic and exophytic. These tumors can also spread by direct extension to the choroid or along the optic nerve beyond the lamina cribrosa to the central nervous system, or by hematogenous or lymphatic spread to distant sites, including bones, bone marrow, and lungs.

CLINICAL MANIFESTATIONS
Retinoblastoma classically presents with leukocoria, a white pupillary reflex (Fig. 502-1), which often is first noticed when a red reflex is not present at a routine newborn or well-child examination or in a flash photograph of the child. Strabismus often is an initial presenting complaint. Decreased vision, orbital inflammation, hyphema, and pupil irregularity can occur with advancing disease. Pain can occur if secondary glaucoma is present. Only approximately 10% of retinoblastoma cases are detected by routine ophthalmologic screening in the context of a positive family history.

DIAGNOSIS
The diagnosis is established by the characteristic ophthalmologic findings of a chalky, white-gray retinal mass with a soft, friable consistency.
Other radiation-related late adverse effects include cataracts, orbital growth deformities, lacrimal dysfunction, and late retinal vascular injury.

Chapter 503 ◆ Gonadal and Germ Cell Neoplasms

Cynthia E. Herzog and Winston W. Huh

EPIDEMIOLOGY
Malignant germ cell tumors (GCTs) and gonadal tumors are rare, with an incidence of 12 cases per 1 million persons younger than 20 yr of age. Most malignant tumors of the gonads in children are GCTs. The incidence varies according to age and sex, although the incidence of GCTs in adolescent males has increased over time. Sacrococcygeal tumors occur predominantly in infant girls. Testicular GCTs occur predominantly before age 4 yr and after puberty. Klinefelter syndrome is associated with an increased risk of mediastinal GCTs; Down syndrome, undescended testes, infertility, testicular atrophy, testicular microlithiasis, testicular dysgenesis syndrome, and inguinal hernias are associated with an increased risk of testicular cancer. The risk of testicular cancer in patients with cryptorchidism is reduced but not eliminated if orchiopexy is performed before 13 yr of age. The risk of testicular GCT is increased in 1st-degree relatives and is highest among monozygotic twins.

PATHOGENESIS
The GCTs and non-GCTs arise from primordial germ cells and coelomic epithelium, respectively. Testicular and sacrococcygeal GCTs arising during early childhood characteristically have deletions at chromosome arms 1p and 6q and gains at 1q, and lack the isochromosome 12p that is highly characteristic of malignant GCTs of adults. Testicular GCT also may demonstrate loss of imprinting. Ovarian GCTs from older girls characteristically have deletions at 1p and gains at 1q and 21. Because GCTs may contain benign and mixed malignant elements in different areas of the tumor, extensive sectioning is essential to confirm the correct diagnosis. The many histologically distinct subtypes of GCTs include teratoma (mature and immature), endodermal sinus tumor, and embryonal carcinoma (Fig. 503-1). Non-GCTs of the ovary include epithelial (serous and mucinous) and sex cord–stromal tumors; non-GCTs of the testicle include sex cord/stromal (e.g., Leydig cell, Sertoli cell) tumors. DICER1 mutations have been observed in nonepithelial ovarian cancers, especially in Sertoli-Leydig tumors.

CLINICAL MANIFESTATIONS AND DIAGNOSIS
The clinical presentation of germ cell neoplasms depends on location. Ovarian tumors often are quite large by the time they are diagnosed (Fig. 503-2). Extragonadal GCTs occur in the midline, including the suprasellar region, pineal region, neck, mediastinum, and retroperitoneal and sacrococcygeal areas (Fig. 503-3). Symptoms relate to mass effect, but the intracranial GCTs often present with anterior and posterior pituitary deficits (see Chapter 497).

The serum α-fetoprotein (AFP) level is elevated with endodermal sinus tumors and may be minimally elevated with teratomas. Infants normally have higher levels of AFP, which fall to normal adult levels by about age 8 mo; consequently, high AFP levels must be interpreted with caution in this age group. Elevation of the β subunit of human chorionic gonadotropin, which is secreted by syncytiotrophoblasts, is seen with choriocarcinoma and germinomas. Lactate dehydrogenase,
Gonadoblastomas often occur in patients with gonadal dysgenesis and all or parts of a Y chromosome. Gonadal dysgenesis is characterized by failure to fully masculinize the external genitalia. If this syndrome is diagnosed, imaging of the gonad with ultrasonography or CT is performed, and surgical resection of the tumor usually is curative. Prophylactic resection of dysgenetic gonads at the time of diagnosis is recommended, because gonadoblastomas, some of which contain malignant GCT elements, often develop. Gonadoblastomas may produce abnormal amounts of estrogen.

Teratomas occur in many locations, presenting as masses. They are not associated with elevated markers unless malignancy is present. The sacrococcygeal region is the most common site for teratomas. Sacrococcygeal teratomas occur most commonly in infants and may be diagnosed in utero or at birth, with most found in girls. The rate of malignancy in this location varies, ranging from <10% in children younger than 2 mo of age to >50% in children older than 4 mo of age.

Germinomas occur intracranially, in the mediastinum, and in the gonads. In the ovary, they are called dysgerminomas; in the testis,
seminomas. They usually are tumor-marker-negative masses despite being malignant. Endodermal sinus or yolk sac tumor and choriocarcinoma appear highly malignant by histologic criteria. Both occur at gonadal and extragonadal sites. Embryonal carcinoma most often occurs in the testes. Choriocarcinoma and embryonal carcinoma rarely occur in the pure form and are usually found as part of a mixed malignant GCT.

Non–germ cell gonadal tumors are very uncommon in pediatrics and occur predominantly in the ovary. Epithelial carcinomas (usually an adult tumor), Sertoli-Leydig cell tumors, and granulosa cell tumors may occur in children. Carcinomas account for about one third of ovarian tumors in females younger than 20 yr of age; most of these occur in older teens and are of the serous or mucinous subtype. Sertoli-Leydig cell tumors and granulosa cell tumors produce hormones that can cause virilization, feminization, or precocious puberty, depending on pubertal stage and the balance between Sertoli cells (estrogen production) and Leydig cells (androgen production). Diagnostic evaluation usually focuses on the chief complaint of inappropriate sex steroid effect and includes hormone measurements, which reflect gonadotropin-independent sex steroid production. Appropriate imaging also is performed to rule out a functioning gonadal tumor. Surgery usually is curative. No effective therapy for nonresectable disease has been found.

**TREATMENT**

Complete surgical excision of the tumor usually is indicated, except for patients with intracranial tumors, where the primary therapy consists of radiation therapy and chemotherapy. For testicular tumors, an inguinal approach is indicated, and complete resection should include the entire spermatic cord. When complete excision cannot be accomplished, preoperative chemotherapy is indicated, with second-look surgery. For completely resected nonseminomatous testicular tumors, there is debate on whether patients can be clinically observed following surgery. For teratomas, both mature and immature, and completely resected malignant tumors of the testes, surgery alone is the treatment. For ovarian tumors, unless the contralateral ovary is obviously also involved by tumor, a fertility-sparing surgery should be performed. Cisplatin-based chemotherapy regimens usually are curative in GCTs that cannot be completely resected, even if metastases are present. However, sex cord–stromal tumors tend to be refractory to chemotherapy. Except for GCTs of the central nervous system, radiation therapy is limited to those tumors that are not amenable to complete excision and are refractory to chemotherapy.

**PROGNOSIS**

The overall cure rate for children with GCTs is >80%. Age is the most predictive factor of survival for extragonadal GCTs. Children older than 12 yr of age have a 4-fold higher risk of death, and a 6-fold higher risk if the tumor is thoracic. Histology has little effect on prognosis. Nonresected extragonadal GCTs have a slightly worse prognosis.

**Bibliography**

Hepatic tumors are rare in children. Primary tumors of the liver account for approximately 1% of malignancies in children younger than 15 yr of age, with an annual incidence of 1.6 cases per 1 million children in the United States. Between 50% and 60% of hepatic tumors in children are malignant, with >65% of these malignancies being hepatoblastomas and most of the remainder being hepatocellular carcinomas. Rare hepatic malignancies include embryonal sarcoma, angiosarcoma, malignant germ cell tumor, rhabdomyosarcoma of the liver, and undifferentiated sarcoma. More common childhood malignancies, such as neuroblastoma, Wilms tumor, and lymphoma, can metastasize to the liver. Benign liver tumors, which usually present in the 1st 6 mo of life, include hemangiomas, hamartomas, and hemangioendotheliomas.

**HEPATOBLASTOMA**

**Epidemiology**

Approximately 100 new cases of hepatoblastoma are diagnosed each yr in the United States. Hepatoblastoma occurs predominantly in children younger than 3 yr of age and the median age of diagnosis is 1 yr. The etiology is unknown. Hepatoblastomas are associated with familial adenomatous polyposis. Alterations in the antigen-presenting cell/β-catenin pathway have been found in most of the tumors evaluated. Hepatoblastomas are also associated with Beckwith-Wiedemann syndrome, hemihyperplasia, and other somatic overgrowth syndromes. Increased expression of insulin-like growth factor 2 secondary to genetic mutations or epigenetic changes is implicated in hepatoblastoma development in patients with Beckwith-Wiedemann syndrome. All children with Beckwith-Wiedemann syndrome or hemihyperplasia should be routinely screened with α-fetoprotein (AFP) levels and abdominal ultrasounds. Prematurity and low birthweight is associated with increased incidence of hepatoblastoma, with the risk increasing as birthweight decreases.

**Pathogenesis**

Hepatoblastoma arises from precursors of hepatocytes and is histologically classified as whole epithelial type, containing fetal or embryonal malignant cells (either as a mixture or as pure elements), and mixed type, containing both epithelial and mesenchymal elements. Histologic classification has a direct correlation with clinical outcome. The pure fetal histology subtype predicts a more favorable outcome and the small cell undifferentiated subtype is associated with normal AFP levels and predicts a worse outcome.

**Clinical Manifestations**

Hepatoblastoma usually presents as a large, asymptomatic abdominal mass. It arises from the right lobe 3 times more often than the left and usually is unifocal. As the disease progresses, fatigue, fever, weight loss, anorexia, vomiting, and abdominal pain may ensue. Rarely, hepatoblastoma presents with hemorrhage secondary to trauma or spontaneous rupture. Metastatic spread of hepatoblastoma most commonly involves regional lymph nodes and the lungs.

**Diagnosis**

A biopsy of liver tumors is necessary to establish the diagnosis. A valuable serum tumor marker, AFP, is used in the diagnosis and monitoring of hepatic tumors. The AFP levels are elevated in almost all hepatoblastomas. Bilirubin and liver enzymes usually are normal. Anemia is common, and thrombocytosis occurs in approximately 30% of patients. Serologic testing for hepatitides B and C should be performed, but the results usually are negative in hepatoblastoma.

Diagnostic imaging should include plain radiographs and ultrasonography of the abdomen to characterize the hepatic mass. Ultrasonography can differentiate malignant hepatic masses from benign vascular lesions. Either CT or MRI is an accurate method of defining the extent of intrahepatic tumor involvement and the potential for surgical resection. Evaluation for metastatic disease should include CT of the chest.

**Treatment**

In general, the cure of malignant hepatic tumors in children depends on complete resection of the primary tumor (Fig. 504-1); as much as 85% of the liver can be resected, with hepatic regeneration noted within 3-4 mo after surgery. Treatment of hepatoblastoma is based on surgery and systemic chemotherapy using cisplatin in combination with vincristine and 5-fluorouracil or doxorubicin. In 30% of cases,
Hepatocellular carcinoma

Epidemiology
Hepatocellular carcinoma occurs mostly in adolescents and often is associated with hepatitis B or C infection. It is more common in East Asia and other areas where hepatitis B is endemic; the incidence has decreased following the introduction of hepatitis B vaccination. In these areas it also tends to occur in a bimodal pattern, with the younger age peak overlapping the age of hepatoblastoma presentation. It also occurs in the chronic form of hereditary tyrosinemia, galactosemia, glycogen storage disease, α1-antitrypsin deficiency, and biliary cirrhosis. Aflatoxin B contamination of food is another risk factor.

Pathogenesis
Hepatocellular carcinoma usually arises in an abnormal or cirrhotic liver and presents as a multicentric, invasive tumor consisting of large pleomorphic cells of epithelial origin. Compared to adults, cirrhosis in children is less common and congenital liver disorders are more common. Hepatocellular carcinomas are classified as classical or fibrolamellar. The fibrolamellar variant occurs more often in adolescent and young adult patients and is not associated with cirrhosis. Although previous reports have suggested that the fibrolamellar type has a better prognosis, more recent data analysis refutes this.

Clinical Manifestations
Hepatocellular carcinoma usually presents as a hepatic mass with abdominal distention and symptoms of anorexia, weight loss, and abdominal pain. Hepatocellular carcinoma can present as an acute abdominal crisis with rupture of the tumor and hemoperitoneum. Metastatic spread usually involves regional lymph nodes and the lungs. The AFP level is elevated in approximately 60% of children. Evidence of hepatitis B and C infection usually is found in endemic areas but not in Western countries or with the fibrolamellar type. Bilirubin usually is normal, but liver enzymes may be abnormal.

Diagnostic imaging should include plain radiographs and ultrasonography of the abdomen to characterize the hepatic mass. Ultrasonography can differentiate malignant hepatic masses from benign vascular lesions. Either CT or MRI is an accurate method of defining the extent of intrahepatic tumor involvement and the potential for surgical resection. Evaluation for metastatic disease should include CT of the chest.

Treatment
Complete tumor resection is crucial for curative treatment. Because of the multicentric origin of hepatocellular carcinoma and underlying liver disease, complete resection is accomplished in only 30-40% of cases. A gross total resection should be attempted at diagnosis when possible; combination chemotherapy following surgery is necessary. For unresectable tumors, chemotherapy followed by surgical assessment is essential; liver transplant is an option for unresectable tumors. Even with complete surgical resection, only 30% of children are long-term survivors. Chemotherapy, including cisplatin, doxorubicin, etoposide, and 5-fluorouracil, has shown some activity against this tumor, but improved long-term outcome has been difficult to achieve. Other techniques, such as cryosurgery, radiofrequency ablation, transarterial chemoembolization, and ethanol injection, are under study as therapy for hepatocellular carcinomas.

Bibliography is available at Expert Consult.
Bibliography
Hemangiomas, the most common benign tumors of infancy, occur in approximately 5-10% of term infants (see Chapter 650). The risk of hemangioma is 3-5 times higher in girls than boys. The risk is doubled in premature infants and 10 times higher in offspring of women who had chorionic villus sampling. Hemangiomas can be present at birth but usually arise shortly after birth and grow rapidly during the 1st yr of life, with slowing of growth in the next 5 yr and involution by 10-15 yr of age.

**CLINICAL MANIFESTATIONS**

More than 50% of all hemangiomas are located in the head and neck region. Most are solitary lesions, but the presence of more than 1 cutaneous lesion increases the likelihood of visceral hemangiomas. The liver is the primary site of visceral involvement; other involved organs include the brain, intestines, and lung. Infantile hemangiomas can be differentiated from other lesions with which they may be confused by the expression of GLUT1. Most hemangiomas require no therapy, but approximately 10% of hemangiomas cause significant impairment and 1% are life-threatening because of their location. Hemangiomas around the airway can cause airway obstruction, and those around the eyes can result in loss of vision. Ulceration is a common complication and can lead to secondary infection. With or without treatment, after involution of a hemangioma, residual skin abnormalities remain. Large hepatic hemangiomas or hemangioendotheliomas may result in hepatomegaly, anemia, thrombocytopenia, and high-output heart failure.

**Kasabach-Merritt syndrome** (see Chapter 650) is characterized by a rapidly enlarging lesion, thrombocytopenia, microangiopathic hemolytic anemia, and coagulopathy as a result of platelet and red blood cell trapping and activation of the clotting system within the vasculature of the hemangioma. This syndrome is associated with kaposiform hemangioendotheliomas or tufted angiomas but not with infantile hemangiomas.

Cutaneous lesions usually can be diagnosed by typical appearance and rapid proliferation. Segmental hemangiomas, or those with geographic localization and some plaque-like features, recently have been shown to have a higher risk of complications and association with developmental abnormalities. A deep lesion may require imaging studies to help differentiate it from a lymphangioma. The presence of a midline hemangioma in the lumbosacral area indicates the need for an MRI to search for underlying asymptomatic neurologic abnormalities. Location also may dictate the need for an ophthalmologic or surgical consultation. An ultrasonographic scan or MRI of the liver should be performed if multiple cutaneous lesions are present.

**TREATMENT**

See Chapter 650.

Bibliography is available at Expert Consult.

---

Lymphatic malformations, including lymphangiomas and cystic hygromas, which arise in the embryonic lymph sac, are the second most common benign vascular tumors in children. About half are located in the head and neck area. Approximately 50% are present at birth, with most presenting by 2 yr of age. There is no gender predisposition. Spontaneous regression has been reported but is not typical.

Lymphatic malformations present as soft, painless masses that transluminate if superficial. Intrathoracic lymphatic malformation can present as symptoms related to a mediastinal mass or pericardial or pleural effusion. Rapid enlargement can occur with infection or hemorrhage. Localized lesions may be surgically resected, but this can be difficult, owing to their infiltrative nature. Recurrence is common with incompletely resected lesions. Aspiration can provide temporary relief in an emergency, such as in the presence of dyspnea, but reaccumulation will occur. Treatment by injection of sclerosing agents, laser therapy, and systemic interferon therapy also has been used. The streptococcal immunotherapeutic agent OK-432 (Picibanil) is the sclerosing agent of choice; its use will prevent the need for surgery in most cases. Bleomycin is also an effective sclerosing agent but has a risk of pulmonary toxicity. It appears to be especially effective for the treatment of macrocystic lymphangiomas of the head and neck.

Rare Tumors

506.1 Thyroid Tumors

Steven G. Waguespack

See Chapter 569.

BENIGN THYROID TUMORS

Benign thyroid tumors represent approximately 75% of all thyroid nodules presenting in the pediatric population. The work-up of a suspected thyroid nodule includes the laboratory assessment of thyroid function, ultrasound to assess the nodule and regional lymph node characteristics, and fine-needle aspiration biopsy under ultrasound guidance for definitive pathologic diagnosis. Nuclear scintigraphy using radioactive iodine (¹³¹I) or ¹²³I-pertechnetate is not recommended in the initial diagnostic evaluation, except in the event of a suppressed thyroid-stimulating hormone (TSH) level.

MALIGNANT THYROID TUMORS

Pediatric thyroid malignancies are rare tumors that include medullary thyroid carcinoma (MTC) and the differentiated thyroid carcinomas (DTCs): papillary thyroid carcinoma (PTC) and follicular thyroid carcinoma. PTC represents the vast majority of thyroid cancers in children, who have an excellent overall prognosis with anticipated survival over decades, even in the presence of metastatic disease at diagnosis. The major established environmental risk factor for the development of PTC is exposure to ionizing radiation.

MTC is a very uncommon disease in childhood that almost always occurs in the context of an autosomal dominant, hereditary endocrine tumor syndrome that arises secondary to activating mutations in the RET (REarranged during Transfection) protooncogene: multiple endocrine neoplasia type 2a (MEN2A) or type 2b (MEN2B). In addition to the almost complete penetrance of MTC in the most common RET mutations, patients with MEN2A and MEN2B have up to a 50% lifetime risk of developing pheochromocytomas. Up to 20% of MEN2A patients will develop primary hyperparathyroidism. Patients with MEN2B do not develop hyperparathyroidism but have a distinct phenotype with a characteristic facial appearance, marfanoid body habitus, and a generalized ganglieneuromatosis, manifested most obviously by the presence of oral mucosal neuromas (Fig. 506-1).
pathognomonic phenotype of MEN2B is not apparent in very early childhood, although an inability to cry tears and constipation represent early clues to diagnosis in these patients.

Children with thyroid cancer usually present with an asymptomatic thyroid mass and/or cervical lymphadenopathy, although children with MEN2 are often diagnosed only after a positive genetic test result or, in the case of MEN2B, after the clinical phenotype is recognized. Lymph node metastases are present in the majority of PTC cases and lung metastases are identified in up to 20% of patients, primarily in those children with a high burden of neck disease.

The primary therapy for thyroid cancer is a total thyroidectomy and a compartment-oriented lymph node dissection, as indicated, performed by a highly experienced thyroid cancer surgeon. In DTC, \(^{131}\text{I}\) is used postoperatively to treat distant metastasis and unresectable residual neck disease. In PTC, the routine use of \(^{131}\text{I}\) is limited to those children who are most likely to benefit from treatment. Children with MTC do not require \(^{131}\text{I}\) therapy. The TSH level is initially suppressed by giving supraphysiologic levothyroxine in the case of DTC, as TSH stimulates DTC tumor growth; the TSH is kept normal in the case of MTC. Long-term follow-up involves monitoring of tumor markers (thyroglobulin in DTC and calcitonin/carcinogenic embryonic antigen in MTC), as well as routine imaging, primarily neck ultrasound.

In MEN2, there are well-documented genotype-phenotype correlations, and the biologic aggressiveness of MTC depends on the hereditary setting in which it develops. With the advent of genetic testing for RET mutations, MTC has become one of the few malignancies that can be cured via early thyroidec- tomy before the cancer becomes metastatic. Recommendations regarding the age at surgery of children who are carriers of a RET mutation are evolving and incorporate clinical testing (ultrasound and calcitonin levels) in addition to knowledge regarding the genotype. Novel oral tyrosine kinase inhibitors are approved by the FDA for the treatment of advanced MTC and DTC in adults.

### 506.2 Melanoma

**Dennis P.M. Hughes and Cynthia E. Herzog**

See Chapter 651.

The incidence of melanoma in persons younger than 20 yr of age in the United States is 4.2 cases per 1 million, with 73% occurring in 15-19 year olds, 17% in 10-14 year olds, and 10% occurring in children younger than 10 yr of age (see Chapter 651). Melanoma is more common among adolescent females than males. In the United States, incident rates of melanoma in younger age groups are increasing, although at a slower rate than in adults. UV light, especially sun exposure, is a well-known risk factor for melanoma in adults, and also contributes to teenage melanoma, as shown by the tendency of lesions to develop on sun-exposed areas in this age group. In younger patients, melanoma does not appear to be associated with sun exposure and often occurs in skin that is not frequently exposed to the sun. Pediatricians should counsel patients regarding avoidance of sun exposure and the use of tanning beds to decrease the risk of later development of melanoma. Patients with fair skin and a family history of melanoma are at particularly high risk. Known risk factors for children are a giant hairy nevus (>10 cm), dysplastic nevus syndrome, and xeroderma pigmentosum. These conditions merit total skin examination at least annually.

Findings of a rapidly enlarging nevus that is dark, has changed colors, has irregular borders, or bleeds easily should raise a concern of melanoma. However, more than half of pediatric melanomas are nonpigmented, and can easily be confused with a wart or other benign finding. Diagnosis is based on pathology, and a punch biopsy is preferred. However, extra care must be taken in the diagnosis of melanoma in children because making the distinction from other lesions, particularly Spitz nevus, can be difficult. Management in a center with expertise in pediatric melanoma may be advisable, especially for anything other than thin melanomas (Breslow thickness of 1 mm or greater).

Prognosis and treatment recommendations have previously been extrapolated from adult data; however, specific prognostic factors for pediatric melanoma are starting to accrue. The initial diagnosis is best made with a punch biopsy. Shave biopsy is specifically discouraged, as this method tends to leave the base of the lesion behind, and specific information about the depth of invasion is lost. Biopsy sites that test positive for melanoma should be reexcised with appropriate margins based on thickness. Lymph node mapping and sentinel node biopsy should also be performed for all melanomas with a Breslow thickness >0.5-1 mm, or any lesions in which the tumor base was not resected. If the sentinel node is positive, a formal lymph node dissection is essential for ensuring the best probability of survival. To date, the treatment of childhood melanoma still mirrors treatment of adult melanoma. High-dose adjuvant interferon shows some efficacy in the treatment of adult melanoma, whereas chemotherapy in combination with biologic agents and vaccine therapy has been used for treatment of distant metastases. Although novel therapies such as targeted B-Raf inhibitors and immune-modulating agents have received regulatory approval for treatment of adult melanoma, their use in children is still investigational.

Bibliography is available at Expert Consult.

### 506.3 Nasopharyngeal Carcinoma

**Cynthia E. Herzog**

Nasopharyngeal carcinoma is rare in the pediatric population but is one of the most common nasopharyngeal tumors in pediatric patients. In adults, the incidence is highest in South China, but it is also high among the Inuit people and in North Africa and Northeast India. In China, it is rare in the pediatric population, but in other populations a substantial proportion of cases occur in the pediatric age group, primarily in adolescents. It occurs in males twice as often as in females and is more common in blacks. In the pediatric population the tumors are more commonly of undifferentiated histology and associated with Epstein-Barr virus. Nasopharyngeal carcinoma is associated with specific human leukocyte antigen types, and other genetic factors may play a role, especially in low-incidence populations.

Most pediatric patients present with advanced locoregional disease manifesting as cervical lymphadenopathy. Epistaxis, trismus, and cranial nerve deficits also may be present. The diagnosis is established from biopsy of the nasopharynx or cervical lymph nodes. In most cases the lactate dehydrogenase level is elevated, but this finding is nonspecific. CT or MRI evaluation of the head and neck is performed to
**Bibliography**

Bibliography
determine the extent of locoregional disease. Chest radiography, CT, bone scan, and liver scan are used to evaluate for metastatic disease. Positron emission tomography scans appear to be useful for monitoring both primary disease and looking for metastases. Epstein-Barr virus DNA levels correlate with disease stage, have prognostic value, and can be used to monitor for recurrence.

Treatment is a combination of chemotherapy and irradiation. Cisplatin given concurrently with radiation, with or without neoadjuvant cisplatin-based chemotherapy, is the standard treatment. The outcome depends on the extent of disease; patients with distant metastases have a very poor prognosis. Using intensity-modulated radiation therapy improves local control and reduces the late adverse effects associated with radiation therapy, including hormonal dysfunction, dental caries, fibrosis, and second malignancies. Use of proton therapy may result in further reduction of adverse effects.

Bibliography is available at Expert Consult.

506.4 Adenocarcinoma of the Colon and Rectum
Cynthia E. Herzog and Winston W. Huh

Colorectal carcinoma (CRC) is rare in the pediatric population with an estimated incidence rate of approximately 1 case per 1 million. Even in patients with predisposing conditions, CRC usually does not present until late adolescence or adulthood. Hereditary nonpolyposis colon cancer (HNPCC) is an autosomal dominant disorder, with germline mutations in DNA mismatch repair genes (MMR) causing DNA repair errors and microsatellite instability. Familial adenomatous polyposis (FAP) and attenuated FAP are autosomal disorders, with germline mutations in the APC gene. In addition to CRC, patients with HNPCC, FAP, and attenuated FAP are predisposed to a number of extracolonic cancers. Desmoid tumors can occur in patients with FAP, whereas patients with HNPCC have an increased risk for tumors involving the genitourinary tract, stomach, and small intestine. MYH-associated polyposis, Peutz-Jeghers syndrome, and juvenile polyposis also predispose to CRC.

Genetic testing is available, and screening for cancer in HNPCC and FAP should begin during childhood or adolescence. Likewise, genetic evaluation for these conditions should be pursued in young patients presenting with colon cancer, even when there is no history of predisposing genetic conditions.

Presenting symptoms include bloody stools or melena, abdominal pain, weight loss, and changes in bowel patterns. In many cases, signs are vague, often resulting in a delay in diagnosis, sometimes not until the disease has reached an advanced stage. The histologic subtype differs from that seen in adults, with the majority of pediatric tumors being either mucinous adenocarcinoma or signet ring cell carcinoma. Treatment consists of surgical resection when possible, with chemotherapy for unresectable tumors. Adequate lymph node removal should be performed at the time of surgical resection of primary tumor. Radiation therapy is useful in the treatment of rectal carcinomas.

Bibliography is available at Expert Consult.

506.5 Adrenal Tumors
Steven G. Waguespack

See Chapters 579 to 581.

Adrenocortical tumors (ACTs) arise from the outer adrenal cortex, whereas pheochromocytomas (PHEOs) derive from the catecholamine-producing chromaffin cells of the adrenal medulla. When catecholamine-producing tumors arise outside of the adrenal medulla, they are called paragangliomas (PGLs). The pathologic categorization of these tumors as benign or malignant does not always correlate well with the clinical behavior, making it difficult to differentiate malignant from benign disease based upon pathology alone. Hence, long-term follow-up is warranted. Because of the greater association with genetic disease, genetic counseling is also advised for all children diagnosed with an ACT or PHEO/PGL.

ACTs are very rare and tend to present before age 5 yr. They have a female predominance and are functional tumors in >90% of cases, primarily producing androgens and causing clinically apparent virilization. ACT may also present as an abdominal mass or pain. In children, ACTs are associated with Li-Fraumeni syndrome (germline inactivating mutations in the TP53 tumor-suppressor gene), Beckwith-Wiedemann syndrome, hemihyperplasia other than that seen as part of Beckwith-Wiedemann syndrome, and, very rarely, congenital adrenal hyperplasia. Other unusual causes of nodular adrenocortical disease, which usually present with Cushingsyndrome, include the Carney complex and macronodular adrenal hyperplasia.

PHEOs/PGLs are rare tumors that are more likely to be bilateral, malignant, and secondary to a heritable tumor syndrome when diagnosed in children. von Hippel-Lindau disease is the most common genetic cause of PHEOs/PGLs in the pediatric population, followed by the familial PGL syndromes caused by mutations in the succinate dehydrogenase gene. MEN2 (types 2A and 2B) and neurofibromatosis type 1 are also in the differential diagnosis, but are mostly associated with a PHEO diagnosis during adulthood. Although hypertension is usually paroxysmal in adults with PHEO, hypertension is usually sustained in children, who may also lack the typical triad of headache, palpitations, and diaphoresis seen commonly in adults. The best screening test for PHEO/PGL is measurement of plasma and/or urine metanephrine levels.

The initial treatment of ACT and PHEO/PGL is surgery. Children with PHEO/PGL require preoperative medical management, typically with α and β blockade. First-line medical therapy for metastatic ACT includes mitotane and chemotherapy with cisplatin, etoposide, and doxorubicin. Metastatic PHEO/PGL has historically been treated with cyclophosphamide, vincristine, and dacarbazine. In cases of both ACT and PHEO/PGL, novel targeted agents are being studied for the treatment of advanced metastatic disease, which is typically nonresponsive to standard chemotherapeutic approaches. Endocrine therapy targeting hormonal overproduction may also be needed to palliate symptoms and improve quality of life.

506.6 Desmoplastic Small Round Cell Tumor
Nidale Tarek and Cynthia E. Herzog

Desmoplastic small round cell tumor is a very rare and aggressive mesenchymal tumor that occurs predominantly in adolescent and young adult males. It is associated with a diagnostic chromosomal translocation between the Ewing tumor gene and the Wilms tumor gene, t(11;22)(p13;q12). Patients typically present with a bulky abdominal mass, multiple peritoneal and omental implants, and symptoms of abdominal sarcomatosis, including pain, ascites, intestinal obstruction, hydronephrosis, and weight loss. Desmoplastic small round cell tumor mainly involves the abdominal cavity but can spread to the lymph nodes, liver, lungs, and bones. Aggressive treatment with combination chemotherapy, debulking surgery, and whole abdominopelvic irradiation results almost universally in a poor outcome. Median survival ranges between 17 and 25 mo, and the 5 yr overall survival remains less than 20%. Alternative treatment options currently under investigation include hyperthermic intraperitoneal chemotherapy and radioimmunotherapy with monoclonal antibodies targeting different surface antigens on tumor cells.

Bibliography
The childhood histiocytoses constitute a diverse group of disorders, which, although individually rare, are frequently severe in their clinical expression. These disorders are grouped together because they have in common a prominent proliferation or accumulation of cells of the monocyte–macrophage system of bone marrow origin. Although these disorders sometimes are difficult to distinguish clinically, accurate diagnosis is essential nevertheless for facilitating progress in treatment. A systematic classification of the childhood histiocytoses is based on histopathologic findings (Table 507-1). A thorough, comprehensive evaluation of a biopsy specimen obtained at the time of diagnosis is essential. This evaluation includes studies such as electron microscopy and immunostaining that may require special sample processing.

### CLASSIFICATION AND PATHOLOGY

Three classes of childhood histiocytosis are defined, based on histopathologic findings. The most well-known childhood histiocytosis, Langerhans cell histiocytosis (LCH), previously known as histiocytosis X, includes the clinical entities of eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease. The normal Langerhans cell is an antigen-presenting cell of the skin. The hallmark of LCH in all forms is the presence of a clonal proliferation of cells of the monocyte lineage containing the characteristic electron microscopic findings of a Langerhans cell. This is the Birbeck granule, a tennis racket–shaped bilamellar granule that, when seen in the cytoplasms of lesion cells in LCH, is diagnostic of the disease. The Birbeck granule expresses a newly characterized antigen, langerin (CD207), which is involved in antigen presentation to T lymphocytes. CD207 expression has been established to be uniformly present in LCH lesions and thus becomes an additional reliable diagnostic marker. It appears more likely that the LCH cell is not actually a (differentiated) Langerhans cell but rather an immature cell of myeloid origin, possibly in an arrested state of development. Nevertheless, the definitive diagnosis of LCH is established by demonstrating CD1a-positivity of lesional cells, which is done using fixed tissue (Fig. 507-1). Lesional cells must be distinguished from normal Langerhans cells of the skin, which are also CD1a-positive but are not diagnostic of LCH. The lesions may contain various proportions of these Langerhans granule-containing CD1a-positive cells, lymphocytes, granulocytes, monocytes, and eosinophils.

In contrast to the prominence of an antigen-presenting cell in LCH, the other common group of histiocytoses are nonmalignant proliferative disorders that are characterized by accumulation of activated antigen-processing cells (macrophages and lymphocytes). These are known as the hemophagocytic lymphohistiocytoses (HLHs). They are the result of uncontrolled hemophagocytosis and uncontrolled activation (upregulation) of inflammatory cytokines with some similarities to the macrophage activation syndrome (see Table 155-5). Tissue infiltration by activated CD8 T lymphocytes, activated macrophages, and hypercytokinemia are classic features (Fig. 507-2). With the characteristic morphology of normal macrophages by light microscopy, these phagocytic cells (Fig. 507-1) are negative for the markers (Birbeck granules, CD1a-positivity, CD207-positivity) characteristic of LCH cells but are CD163-positive.

The 2 major forms of hemophagocytic lymphohistiocytosis have indistinguishable pathologic findings but are very important to distinguish from one another because of implications for both treatment and for prognosis. One is familial hemophagocytic lymphohistiocytosis (FHLH), originally named familial erythrophagocytic lymphohistiocytosis, which is an autosomal recessive disorder and represents approximately 25% of patients with HLH. Genes are known for 4 of the 5 FHLH syndromes; these mutations affect the ability of T lymphocytes and natural killer cells to synthesize and release perforin and granzymes, thus reducing cytotoxic granule formation. The other is the infection-associated hemophagocytic syndrome, also called secondary hemophagocytic lymphohistiocytosis (Table 507-2). Both

Noninfectious causes that may trigger secondary HLH include drugs (phenytoin, highly active antiretroviral therapy), bone marrow transplantation, chemotherapy, autoimmune diseases, inflammatory bowel disease, and immunodeficiency states (DiGeorge syndrome, Bruton agammaglobulinemia, severe combined immunodeficiency syndrome, chronic granulomatous disease, cancer).

These diseases together comprise HLH (Table 507-3 and Fig. 507-3). Multiple different steps in granule formation and release by cytotoxic T cells, when inhibited by genetic mutation, can result in primary HLH (Fig. 507-3, bottom). In an analogous way, a trigger (e.g., infection) can result in secondary HLH (Fig. 507-3, top).

The mixed cellular lesions of both LCH and HLH are increasingly believed to point to these being disorders of immune regulation resulting from either an unusual and unidentified antigenic stimulation and/or an abnormal and defective cellular immune response. Mutations in the perforin (PRF1) gene or the MUNC13-4 gene are the most common causes of defective function of the cytotoxic lymphocytes whose activity is inhibited in FHLH. Some cases of LCH demonstrate clonality of individual lesions. In LCH, a mutated form of the BRAF gene has been identified in many patients; its pathophysiologic significance is being

**Figure 507-3 Inborn errors in the cytotoxic activity of lymphocytes.** Top: Schematic diagram of the immune mechanisms leading to the occurrence of a hemophagocytic syndrome. Following a viral infection, antigen-specific CD8+ T lymphocytes undergo massive expansion and activation and secrete high levels of interferon (IFN)-γ. The overwhelming activated effector cells induce excessive macrophage activation and pro-inflammatory cytokine production including tumor necrosis factor (TNF-α) and interleukin-6 (IL-6). Macrophages spontaneously phagocytose blood elements (here shown: platelets, red blood cells, and a polymorphonuclear cell). Activated lymphocytes and macrophages infiltrate various organs, resulting in massive tissue necrosis and organ failure. Bottom: The genetic defects causing hemophagocytic lymphohistiocytic syndrome (HLH) affect a precise step of the cytotoxic machinery, i.e. granule content, docking, priming, or fusion. Only the defects causing Griscelli syndrome (GS) and familial hemophagocytic lymphohistiocytosis (FHL) are shown. (From Pachlopnik Schmid J, Cote M, Menager MM, et al: Inherited defects in cytotoxic lymphocyte activity. Immunol Rev 235:10-23, 2010.)
assessed. The BRAF mutation suggests both that there is an autonomous proliferative element to the disease and that there may potentially be a new avenue for therapeutic approaches.

In addition to these two most common forms of childhood histiocytosis, LCH and HLH, a number of rarer diseases are also included under this rubric, because they have in common various abnormalities of these cell populations of myeloid origin. These other diseases include juvenile xanthogranuloma, in which the lesional histiocytes are vacuolated, with foamy cytoplasm, and the lesions evolve into mixed granulomas also containing eosinophils, lymphocytes, and other cells. Another rare histiocytosis is Rosai-Dorfman disease, also known as sinus histiocytosis with massive lymphadenopathy. Packing of sinusoids of the lymph nodes with histiocytes that are hemophagocytic characterizes Rosai-Dorfman disease, although extranodal involvement is not uncommon. The etiology of these 2 diseases is unknown. Finally, there is also a group of unequivocal malignancies of cells of monocyte–macrophage lineage. By this definition, acute mononocytic leukemia and true malignant histiocytosis are included among the class III histiocytoses (see Chapter 495). True neoplasms of Langerhans cells, while extremely rare, have been reported.

**507.1 Langerhans Cell Histiocytosis**

*Stephan Ladisch*

### CLINICAL MANIFESTATIONS

LCH has an extremely variable presentation. The skeleton is involved in 80% of patients and may be the only affected site, especially in children older than 5 yr of age. Bone lesions may be single or multiple and are seen most commonly in the skull (Fig. 507-4). Other sites include the pelvis, femur, vertebra, maxilla, and mandible. They may be asymptomatic or associated with pain and local swelling. Involvement of the spine may result in collapse of the vertebral body, which can be seen radiographically, and may cause secondary compression of the spinal cord. In flat and long bones, osteolytic lesions with sharp borders occur and no evidence exists of reactive new bone formation until the lesions begin to heal. Lesions that involve weight-bearing long bones may result in pathologic fractures. Chronically draining, infected ears are commonly associated with destruction in the mastoid area. Bone destruction in the mandible and maxilla may result in teeth that, on radiographs, appear to be free floating. With response to therapy, healing may be complete.

Approximately 50% of patients experience skin involvement at some time during the course of disease, usually as a hard-to-treat scaly, papular, seborrheic dermatitis of the scalp, diaper, axillary, or posterior auricular regions. The lesions may spread to involve the back, palms, and soles. The exanthem may be petechial or hemorrhagic, even in the absence of thrombocytopenia. Localized or disseminated lymphadenopathy is present in approximately 33% of patients. Hepatosplenomegaly occurs in approximately 20% of patients. Various degrees of hepatic malfunction may occur, including jaundice and ascites.

Exophthalmos, when present, often is bilateral and is caused by retroorbital accumulation of granulomatous tissue. Gingival mucous membranes may be involved with infiltrative lesions that appear superficially like candidiasis. Otitis media is present in 30–40% of patients; deafness may follow destructive lesions of the middle ear. In 10–15% of patients, pulmonary infiltrates are found on radiography. The lesions may range from diffuse fibrosis and disseminated nodular infiltrates to diffuse cystic changes. Rarely, pneumothorax may be a complication. If the lungs are severely involved, tachypnea and progressive respiratory failure may result.

Pituitary dysfunction or hypothalamic involvement may result in growth retardation. In addition, patients may have diabetes insipidus; patients suspected of having LCH should demonstrate the ability to concentrate their urine before going to the operating room for a biopsy. Rarely, panhypopituitarism may occur. Primary hypothyroidism as a result of thyroid gland infiltration also may occur.

Patients with multisystem disease who are affected more severely are those who have systemic manifestations, including fever, weight loss, malaise, irritability, and failure to thrive. These systemic manifestations will distinguish between patients who are at high risk of mortality (i.e., “risk organ”-positive patients), and those without, who are at low risk (i.e., “risk organ”-negative patients). The risk organs are liver, spleen hematopoietic system, and lung. The distinction is important for deciding the intensity of the treatment approach and has been incorporated into standard treatment approaches for LCH, as delineated in the Histiocyte Society protocols. Bone marrow involvement may cause anemia and thrombocytopenia. Two uncommon but serious manifestations of LCH are hepatic involvement (leading to fibrosis and cirrhosis) and a peculiar central nervous system (CNS) involvement characterized by ataxia, dysarthria, and other neurologic symptoms. Hepatic involvement is associated with multisystem disease that is often already present at the time of diagnosis. In contrast, the CNS involvement, which is progressive and histopathologically characterized by gliosis, and for which no treatment is known, may be observed only many years after the initial diagnosis of LCH, which itself may have consisted only of mild bone disease. Neither of these manifestations evidences Langerhans cells or Birbeck granules, and both are suspected to be driven initially by cytokine abnormalities.

After tissue biopsy, which is diagnostic and is easiest to perform on skin or bone lesions, a thorough clinical and laboratory evaluation should be undertaken. This should include a series of studies in all patients (complete blood cell count, liver function tests, coagulation studies, skeletal survey, chest radiograph, and measurement of urine osmolality). In addition, detailed evaluation of any organ system that has been shown to be involved by physical examination or by these studies should be performed to establish the extent of disease before initiation of treatment.

**TREATMENT AND PROGNOSIS**

The clinical course of single-system disease (usually bone, lymph node, or skin) generally is benign, with a high chance of spontaneous remission. Therefore, treatment should be minimal and should be directed at arresting the progression of a bone lesion that could result in permanent damage before it resolves spontaneously. Curettage or, less often, steroid injection or low-dose local radiation therapy (5-6 Gy) may accomplish this goal. Multisystem disease, in contrast, should be treated with systemic multiagent chemotherapy. Several different regimens have been proposed, but central elements are the inclusion of vinblastine and steroids, both of which have been found to be very effective in treating LCH. Etoposide has more recently been excluded from standard treatment of multisystem LCH, while treatment of multisystem LCH includes therapy with multiple agents, designed to reduce mortality, reactivation of disease, and long-term consequences.
The response rate to therapy is now quite high, and mortality in severe LCH has been substantially reduced by multiagent chemotherapy, especially if the diagnosis is made accurately and expeditiously. The most recent treatment results, employing lengthened continuation therapy, show a greater than 85% survival rate in severe multisystem disease and a reduced rate of relapse. Experimental therapies, suggested only for unresponsive disease (often in very young children with multisystem disease and organ dysfunction who have not responded to multiagent initial treatment), include immunosuppressive therapy with cyclosporine/antithymocyte globulin and possibly imatinib, 2-chlorodeoxyadenosine, and stem cell transplantation. Late (fibrotic) complications, whether hepatic or pulmonary, are irreversible and require organ transplantation to be definitively treated. Current treatment approaches and experimental protocols for both LCH and HLH can be obtained at the website for the Histiocyte Society (http://www.histiocytesociety.org). An unresolved problem is treatment of the (usually late-onset) severe, progressive, and intractable LCH-associated neurodegenerative syndrome.

507.2 Hemophagocytic Lymphohistiocytosis

Stephan Ladisch

(See “Classification and Pathology” above.)

CLINICAL MANIFESTATIONS

The major forms of HLH, FHLF and secondary HLH, have a remarkably similar presentation consisting of a generalized disease process, most often with fever (90-100%), maculopapular and/or petechial rash (10-60%), weight loss, and irritability (see Tables 507-4 and 507-5). FHLH also is characterized by severe immunodeficiency. Children with FHLH generally are younger than 4 yr of age, and children with secondary HLH may present at an older age, but both forms are recognized as presenting at any age. Physical examination often reveals hepatosplenomegaly (70-100%), lymphadenopathy (20-50%), respiratory distress (40-90%), jaundice, and symptoms of CNS involvement (~50%) that are not unlike those of aseptic meningitis or acute demyelinating encephalomyelitis (see Chapter 600.3). MRI may demonstrate systemic T2-weighted/FLAIR hyperintensities in gray and white matter and in supratentorial and infratentorial regions. The cerebrospinal fluid pleocytosis (50-90%) in CNS involvement of FHLH is characterized by cells that are the same phagocytic macrophages found in the peripheral blood or bone marrow. The diagnosis can be made either on the basis of a molecular (genetic) defect (see “Treatment and Prognosis” below) or on the pathologic findings of hemophagocytosis in bone marrow biopsy, and is suggested by clinical findings of fever, splenomegaly, and associated laboratory findings (in both forms of HLH), including hypertriglyceridemia (80-100%), hypofibrinogenemia (65-85%), elevated levels of hepatic enzymes (30-90%), extremely elevated levels of circulating soluble interleukin-2 receptors released by the activated lymphocytes, very high levels of serum ferritin (often >10,000), and cytopenias (in ~90-100%; especially pancytopenia from hemophagocytosis in the marrow). Hemophagocytosis is not specific for HLH without other features. In addition, in some subgroups of HLH perforin assays may be normal. In the absence of genetic mutations, the diagnosis of HLH is based on a set of specific criteria formulated by the Histiocyte Society, the presence of 5 of 8 of which is considered diagnostic of HLH (see Table 507-4): fever, splenomegaly, cytopenia of 2 cell lines, hypertriglyceridemia or hypofibrinogenemia, hyperferritinemia, elevated soluble CD25 (interleukin-2 receptor), reduced or absent natural killer cells, and bone marrow, cerebrospinal fluid, or lymph node evidence of hemophagocytosis. There are patients with FHLH who have no known identifiable gene mutation. No absolute clinical or laboratory distinction can be made between FHLH and secondary HLH, although genetic markers for FHLH can complement a positive family history for other affected children.

In the absence of either (1) documented genetic defect coupled with defective NK cell cytotoxicity or (2) frank hemophagocytosis, great care should be taken in making the diagnosis of (secondary) HLH, with its implication of the use of cytotoxic chemotherapy. This is because the otherwise nonspecific criteria (indicative of inflammation) used to diagnose HLH can also be seen in diseases that are not always associated with hemophagocytosis (such as an overwhelming acute viral infection without T cell overactivation) in which the cytotoxic and immunosuppressive therapy used in treating HLH might be contraindicated.

TREATMENT AND PROGNOSIS

The diagnostic distinction between FHLH and secondary HLH sometimes can be based on the acute onset of secondary HLH in the presence of a documented infection. In this case, treatment of the underlying infection, coupled with supportive care, is critical. If the diagnosis is made in a setting of iatrogenic immunodeficiency, immunosuppressive treatment should be withdrawn and supportive care should be instituted along with specific therapy for underlying infection. When FHLH (gene mutations in perforin or Munc13-4 proteins) is diagnosed or is suspected together with no documentation of an infection, therapy currently includes etoposide, corticosteroids, and intrathecal methotrexate. It should be stressed that pancytopenia is not a

contraindication to cytotoxic therapy in FHLH. Some recommend antithymocyte globulin and cyclosporine for maintenance therapy. Nevertheless, even with chemotherapy, FHLH remains ultimately fatal, often after a relapse of the disease. Allogeneic stem cell transplantation is effective in curing approximately 60% of patients with FHLH.

In contrast, in secondary HLH, it is critical that the underlying disease (e.g., infection, malignancy, or other) be identified and successfully treated. In many cases, such as when an infection can be documented and effectively treated, the prognosis may be excellent without any other specific treatment. However, when a treatable infection or other cause cannot be documented, which is the case in many patients presumed to have secondary HLH, the prognosis may be as poor as that of FHLH, and an identical chemotherapeutic approach, including etoposide, is recommended, even in the face of cytopenias. It is theorized that in both cases, by its cytotoxic effect on macrophages, etoposide interrupts cytokine production, the hemophagocytic process, and the accumulation of macrophages, all of which may contribute to the pathogenesis of infection-associated hemophagocytic syndrome. A broad spectrum of infectious agents, including viruses (e.g., cytomegalovirus, Epstein-Barr virus, human herpesvirus 6), fungi, protozoa, and bacteria, may trigger secondary HLH, often in the setting of immunodeficiency (see Table 507-2). A thorough evaluation for infection should be undertaken in immunodeficient patients with hemophagocytosis. The same syndrome may be identified in conjunction with a rheumatologic disorder (e.g., systemic lupus erythematosus, Kawasaki disease) or a neoplasm (leukemia); in these cases, effective treatment of the underlying disease may cause resolution of the hemophagocytosis. In some patients, interferon and intravenous immunoglobulin have been effective.

507.3 Other Histiocytoses

Stephan Ladisch

Other rare histiocytoses are appropriately named for their clinical presentation. Examples include xanthogranuloma in juvenile xanthogranuloma and striking lymphadenopathy in Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy). Juvenile xanthogranuloma may require systemic treatment with cytotoxic chemotherapy if the disease is disseminated. Rosai-Dorfman disease is usually not treated, although the massive lymphadenopathy may require treatment because of its tendency to cause physical obstruction. Acute monocytic leukemia and true malignant histiocytosis are included because they are unequivocal malignancies of the monocyte-macrophage lineage; they are discussed in Chapter 490.

Section 1
Glomerular Disease

Chapter 508
Introduction to Glomerular Diseases

508.1 Anatomy of the Glomerulus
Cynthia G. Pan and Ellis D. Avner

The kidneys lie in the retroperitoneal space slightly above the level of the umbilicus. They range in length and weight, respectively, from approximately 6 cm and 24 g in a full-term newborn to ≥12 cm and 150 g in an adult. The kidney (Fig. 508-1) has an outer layer, the cortex, which contains the glomeruli, proximal and distal convoluted tubules, and collecting ducts; and an inner layer, the medulla, that contains the straight portions of the tubules, the loops of Henle, the vasa recta, and the terminal collecting ducts (Fig. 508-2).

The blood supply to each kidney usually consists of a main renal artery that arises from the aorta; multiple renal arteries can occur. The main artery divides into segmental branches within the medulla, becoming the interlobar arteries that pass through the medulla to the corticomedullary junction. At this point, the interlobar arteries branch to form the arcuate arteries, which run parallel to the surface of the kidney. Interlobular arteries originate from the arcuate arteries and give rise to the afferent arterioles of the glomeruli. Specialized muscle cells in the wall of the afferent arteriole and specialized distal tubular cells adjacent to the glomerulus (macula densa) form the juxtaglomerular apparatus that controls the secretion of renin. The afferent arteriole divides into the glomerular capillary network, which then recombines into the efferent arteriole (see Fig. 508-2). The juxtamедullary efferent arterioles are larger than those in the outer cortex and provide the blood supply, as the vasa recta, to the tubules and medulla.

Each kidney contains approximately 1 million nephrons (each consisting of a glomerulus and associated tubules). There is a large distribution of “normal nephron number” in humans, with the mean ±2 SD ranging from 200,000 to 2 million nephrons/kidney. This variation can have major pathophysiologic significance as a risk factor for the later development of hypertension and progressive renal dysfunction.

In humans, formation of nephrons is complete at 36-40 wk of gestation, but functional maturation with tubular growth and elongation continues during the 1st decade of life. Because new nephrons cannot be formed after birth, any disease that results in progressive loss of nephrons can lead to renal insufficiency. A decreased number of nephrons secondary to low birthweight, prematurity, and/or unknown genetic or environmental factors has been implicated as a significant risk factor for the development of primary hypertension and progressive renal dysfunction in adulthood. Low nephron number presumably results in hyperfiltration and eventual sclerosis of “overworked” nephron units.

The glomerular network of specialized capillaries serves as the filtering mechanism of the kidney. The glomerular capillaries are lined by endothelial cells (Fig. 508-3) and have very thin cytoplasm that contains many holes (fenestrations). The glomerular basement membrane (GBM) forms a continuous layer between the endothelial and mesangial cells on one side and the epithelial cells on the other. The membrane has 3 layers: a central electron-dense lamina densa; the lamina rara interna, which lies between the lamina densa and the endothelial cells; and the lamina rara externa, which lies between the lamina densa and the epithelial cells. The visceral epithelial cells cover the capillary and project cytoplasmic foot processes, which attach to the lamina rara externa. Between the foot processes are spaces or filtration slits. The

![Figure 508-1 Gross morphology of the renal circulation. (From Pitts RF: Physiology of the kidney and body fluids, ed 3, Chicago, 1974, Year Book Medical Publishers.)](image1)

![Figure 508-2 Comparison of the blood supplies of cortical and juxtamедullary nephrons. (From Pitts RF: Physiology of the kidney and body fluids, ed 3, Chicago, 1974, Year Book Medical Publishers.)](image2)
Kidney function is best measured as glomerular filtration rate (GFR). As the blood passes through the glomerular capillaries, the plasma is filtered through the glomerular capillary walls. The ultrafiltrate, which is cell free, contains all of the substances in plasma (electrolytes, glucose, phosphate, urea, creatinine, peptides, low-molecular-weight proteins) except proteins having a molecular weight of ≥68 kDa (such as albumin and globulins). The filtrate is collected in Bowman’s space and enters the tubules. There its composition is modified by tightly regulated secretion and absorption of solute and fluid by the multiple tubular segments of the nephron and the ductal system, until it exits the kidney, via the ureter, as urine.

Glomerular filtration is the net result of opposing forces applied across the capillary wall. The force for ultrafiltration (glomerular capillary hydrostatic pressure) is a result of systemic arterial pressure, modified by the tone of the afferent and efferent arterioles. The major force opposing ultrafiltration is glomerular capillary oncotic pressure, created by the gradient between the high concentration of plasma proteins within the capillary and the almost protein-free ultrafiltrate in Bowman’s space. Filtration may be modified by the rate of glomerular plasma flow, the hydrostatic pressure within Bowman’s space, and/or the permeability of the glomerular capillary wall.

Although glomerular filtration begins at approximately the 6th wk of fetal life, kidney function is not necessary for normal intruterine homeostasis because the placenta serves as the major fetal excretory organ. After birth, the GFR increases until renal growth ceases (by age ~18-20 yr in most people). To compare GFRs of children and adults, the GFR is standardized to the body surface area (1.73 m²) of an “ideal” 70-kg adult. Even after correction for surface area, the GFR of a child does not approximate adult values until the 3rd yr of life (Fig. 508-5). The GFR may be estimated by measurement of the serum creatinine level. Creatinine is derived from muscle metabolism. Its production is relatively constant, and its excretion is primarily through glomerular filtration. In contrast to the concentration of blood urea nitrogen, which is affected by state of hydration and nitrogen balance, the serum creatinine level is primarily influenced by muscle mass and the level of glomerular function. The serum creatinine is of value only in estimating the GFR under steady-state conditions. A patient can have a normal serum creatinine level without effective renal function very shortly after the onset of acute renal failure with anuria. In this clinical setting, serum creatinine is an insensitive measure of decreased renal function because its level does not rise above normal until GFR falls by 30-40%.

The precise measurement of the GFR is accomplished by quantitatively determining the clearance of a substance that is freely filtered across the capillary wall and is neither reabsorbed nor secreted by the tubules. The clearance (Cₜ) of such a substance is the volume of plasma that, when completely cleared of the contained substance, would yield an equal

---

**Figure 508-3** Electron micrograph of the normal glomerular capillary (Cap) wall demonstrating the endothelium (En) with its fenestrations (f), the glomerular basement membrane (B) with its central dense layer, and adjoining lamina rara interna (LRI) and externa (LRE) (white arrow), and the epithelial cell foot processes (fp) with their thick cell coat (c). The glomerular filtrate passes through the endothelial fenestrae, crosses the basement membrane, and passes through the filtration slits (black arrow) between the epithelial cell foot processes to reach the urinary space (US) (×60,000). J is the junction between 2 endothelial cells. (From Farquhar MG, Kanwar YS: Functional organization of the glomerulus: state of the science in 1979. In Cummings NB, Michael AF, Wilson CB, editors: Immune mechanisms in renal disease, New York, 1982, Plenum.)

**Figure 508-4** Schematic depiction of the glomerulus and surrounding structures.

mesangium (mesangial cells and matrix) lies between the glomerular capillaries on the endothelial cell side of the GBM and forms the medial part of the capillary wall. The mesangium may serve as a supporting, stalk-like structure for the glomerular capillaries and probably has a role in the regulation of glomerular blood flow, filtration, and the removal of macromolecules (such as immune complexes) from the glomerulus. Bowman’s capsule, which surrounds the glomerulus, is composed of a basement membrane, which is continuous with the basement membranes of the glomerular capillaries and the proximal tubules, and the parietal epithelial cells, which are adjacent to the visceral epithelium (Fig. 508-4).

## 508.2 Glomerular Filtration

_Cynthia G. Pan and Ellis D. Avner_

Kidney function is best measured as glomerular filtration rate (GFR).
Bibliography

quantity of that substance excreted in the urine over a specified time. Renal clearance is calculated by the following formula:

\[ C_s = \frac{U_s \times V}{P_s} \]

where \( C_s \) equals the clearance of substance \( s \), \( U_s \) reflects the urinary concentration of \( s \), \( V \) represents the urinary flow rate, and \( P_s \) equals the plasma concentration of \( s \). To correct the clearance for individual body surface area, the formula is:

Corrected clearance (mL/min/1.73 m\(^2\))

\[ C_{\text{corr}} = \frac{C_s \times 1.73}{\text{Surface area (m}\(^2\))} \]

The GFR is optimally measured by the clearance of inulin, a fructose polymer having a molecular weight of approximately 5 kDa. Because the inulin clearance technique is cumbersome for use in clinical practice, the GFR is commonly estimated by the clearance of endogenous creatinine. Formulas that estimate creatinine clearance accurately in clinical settings have been useful tools in patient care. The “bedside” Schwartz formula is the most widely used pediatric formula and is based on the serum creatinine, patient height, and an empirical constant. The accuracy of this equation is further improved utilizing an additional endogenous marker, cystatin C, in addition to serum creatinine. Cystatin C is a 13.6 kDa protease inhibitor produced by nucleated cells. It continues to be tested as a clinical tool to completely replace creatinine-based formulas, as it has distinct advantages in estimating GFR. Unlike creatinine, cystatin C is unaffected by sex, height, muscle mass, bilirubin, or red blood cell hemolysis, and is not secreted by the renal tubules under any conditions.

The absence of plasma proteins larger than the size of albumin from the glomerular filtrate confirms the effectiveness of the glomerular capillary wall as a filtration barrier. Major factors restricting the filtration of these and other macromolecules include their size and their ionic charge. Morphologic studies suggest that the size-selective filtration barrier resides within the GBM. The endothelial cell, basement membrane, and epithelial cell of the glomerular capillary wall all possess strong negative ionic charges (heparan sulfate and glycoproteins containing sialic acid). Proteins in the blood have a relatively low isoelectric point, carry a net negative charge, and are repelled by the negatively charged sites of the glomerular capillary wall, thus restricting filtration.

**PATHOGENESIS**

Glomerular injury may be a result of genetic, immunologic, perfusion, or coagulation disorders. Genetic disorders of the glomerulus may result from mutations in DNA exons encoding proteins located within the glomerulus, interstitium, or tubular epithelium; mutations in regulatory genes controlling DNA transcription; abnormal posttranscriptional modification of RNA transcripts; or abnormal posttranslational modification of proteins. Immunologic injury to the glomerulus results in **glomerulonephritis**, which is a generic term for several diseases, but more precisely a histopathologic term defining inflammation of the glomerular capillaries. Evidence that glomerulonephritis is caused by immunologic injury includes morphologic and immunopathologic similarities to experimental immune-mediated glomerulonephritis; the demonstration of immune reactants (immunoglobulin, complement) in glomeruli; abnormalities in serum complement; and the finding of autoantibodies (anti-GBM) in some of these diseases (Fig. 508-6). There appear to be 2 major mechanisms of immunologic injury: glomerular deposition of circulating antigen–antibody immune complexes and interaction of antibody with glomerular antigens in situ. In the latter circumstance, the antigen may be a normal component of the glomerulus (the noncollagenous domain [NC-1] of type IV collagen).
Bibliography

collagen, a putative antigen in human anti-GBM nephritis) or an antigen that has been deposited in the glomerulus.

In immune complex–mediated diseases, antibody is produced against, and combines with, a circulating antigen that is usually unrelated to the kidney (see Fig. 508-6). The immune complexes accumulate in GBMs and activate the complement system, leading to immune injury. Acute serum sickness in rabbits is produced by a single intravenous injection of bovine albumin. Within 1 wk after injection, a rabbit produces antibody against bovine albumin, and the antigen remains in the blood in high concentration. As antibody enters the circulation, it forms immune complexes with antigen. Although the amount of antigen in the circulation exceeds that of antibody (antigen excess), the complexes formed are small, remain soluble in the circulation, and are deposited in glomeruli. The processes involved in glomerular localization are not well understood but include characteristics of the complex (concentration, charge, size) and/or the glomerulus (mesangial trapping, negatively charged capillary wall); hydrodynamic forces; and the influence of various chemical mediators (angiotensin II, prostaglandins).

With deposition of immune complexes in glomeruli, rabbits develop an acute proliferative glomerulonephritis. Immunofluorescence microscopy demonstrates granular (“lumpy-bumpy”) deposits containing immunoglobulin and complement in the glomerular capillary wall. Electron microscopic studies show these deposits to be on the epithelial side of the GBM and in the mesangium. For the next few days, as additional antibody enters the circulation, the antigen is ultimately removed from the circulation and the glomerulonephritis subsides.

An example of in situ antigen–antibody interaction is anti–GBM antibody disease, in which antibody reacts with antigen(s) of the GBM. Immunopathologic studies reveal linear deposition of immunoglobulin and complement along the GBM in Goodpasture syndrome (see Chapter 517) and certain types of rapidly progressive glomerulonephritis (see Chapter 516).

The inflammatory reaction that follows immunologic injury results from activation of 1 or more mediator pathways. The most important of these is the complement system, which has 2 initiating sequences: the classic pathway, which is activated by antigen–antibody immune complexes, and the alternative or properdin pathway, which is activated by polysaccharides and endotoxin. These pathways converge at C3; from that point on, the same sequence leads to lysis of cell membranes (see Chapter 133). The major noxious products of complement activation are produced after activation of C3 and include anaphylatoxin (which stimulates contractile proteins within vascular walls and increases vascular permeability) and chemotactic factors (C5a) that recruit neutrophils and perhaps macrophages to the site of complement activation, leading to consequent damage to vascular cells and basement membranes. Therapeutic agents to block the antibody production and components of the complement cascade are available and may provide additional tools to treat immune-mediated kidney injury (see Chapters 514 and 518).

The coagulation system may be activated directly, after endothelial cell injury that exposes the thrombogenic subendothelial layer (thereby initiating the coagulation cascade), or it may be activated indirectly, after complement activation. Consequently, fibrin is deposited within glomerular capillaries or within Bowman’s space as crescents. Activation of the coagulation cascade can also activate the kinin system, which produces additional chemotactic and anaphylatoxin-like factors.

Proliferation of glomerular cells occurs in most forms of glomerulonephritis and may be generalized (involving all glomeruli) or focal (involving only some glomeruli and sparing others). Within a single glomerulus, proliferation may be diffuse (involving all parts of the glomerulus) or segmental (involving only 1 or more tufts, but not others). Proliferation commonly involves the endothelial and mesangial cells and is often associated with an increase in the mesangial matrix (see Fig. 508-6). Mesangial proliferation can result from deposition of immune complex within the mesangium. The resultant increase in cell size and number, and production of mesangial matrix, can increase glomerular size and narrow the lumens of glomerular capillaries, leading to renal insufficiency.

Crescent formation in Bowman’s space (capsule) is a result of proliferation of parietal epithelial cells and is often associated with clinical signs of renal dysfunction. Crescents develop in several forms of glomerulonephritis (termed rapidly progressive or crescentic; see Chapter 516) and are a characteristic response to deposition of fibrin in Bowman’s space. Newly formed crescents contain fibrin, proliferating epithelial cells of Bowman’s space, basement membrane-like material produced by these cells, and macrophages that might have a role in the genesis of glomerular injury. Over the subsequent days to weeks, the crescent is invaded by connective tissue and becomes a fibroepithelial crescent. This process generally results in glomerular obsolescence and the clinical development of chronic renal failure. Crescent formation is often associated with glomerular cell death. The necrotic glomerulus has a characteristic eosinophilic appearance and usually contains nuclear remnants. Crescent formation is usually associated with generalized proliferation of the mesangial cells and with either immune complex or anti–GBM antibody deposition in the glomerular capillary wall.

Certain forms of acute glomerulonephritis show glomerular exudation of blood cells, including neutrophils, eosinophils, basophils, and mononuclear cells. The thickened appearance of GBM can result from a true increase in the width of the membrane (as seen in membranous glomerulopathy; see Chapter 512), from massive deposition of immune complexes that have staining characteristics similar to the membrane (as seen in systemic lupus erythematosus; see Chapter 514), or from the interposition of mesangial cells and matrix into the subendothelial space between the endothelial cells and the GBM. The last can give the basement membrane a split appearance, as seen in type I membranoproliferative glomerulonephritis (see Chapter 513) and other diseases.

Sclerosis refers to the presence of scar tissue within the glomerulus. Occasionally, pathologists use this term to refer to an increase in mesangial matrix.

Tubulointerstitial fibrosis is present in all patients who have glomerular disease and who develop progressive renal injury. This fibrosis is initiated by injury to either the glomeruli, which, if severe, may secondarily involve the tubules, or direct injury to the tubules themselves. Tubular injury recruits mononuclear cell infiltrate, which releases a variety of soluble factors that have fibrosis-promoting effects. Matrix proteins of the renal interstitium begin to accumulate, leading to eventual destruction of renal tubules and peritubular capillaries. The actual transformation of tubular epithelium to mesenchymal tissue can contribute to progressive tubulointerstitial fibrosis, a process termed epithelial-mesenchymal transformation.

Bibliography
Hematuria is defined as the presence of at least 5 red blood cells (RBCs) per microliter of urine and occurs with a prevalence of 0.5–2.0% among school-age children. Quantitative studies demonstrate that normal children can excrete more than 500,000 RBCs per 12 hr period; this increases with fever and/or exercise. In the clinical setting, qualitative estimates are provided by a urinary dipstick that uses a very sensitive peroxidase chemical reaction between hemoglobin (or myoglobin) and a colorimetric chemical indicator impregnated on the dipstick. Chemstrip (Boehringer Mannheim), a common commercially available dipstick, is capable of detecting 3–5 RBCs/µL of unspun urine. The presence of 10–50 RBCs/µL may suggest underlying pathology, but significant hematuria is generally considered as >50 RBCs/µL. False-negative results can occur in the presence of formalin (used as a urine preservative) or high urinary concentrations of ascorbic acid (i.e., in patients with vitamin C intake >2000 mg/day). False-positive results may be seen in a child with an alkaline urine (pH > 8), or more commonly following contamination with oxidizing agents such as hydrogen peroxide used to clean the perineum before obtaining a specimen. Microscopic analysis of 10–15 mL of freshly voided and centrifuged urine is essential in confirming the presence of RBCs suggested by >10 RBCs/µL, or a 1+ positive urinary dipstick reading.

Red urine without RBCs is seen in a number of conditions (Table 509-1). Clinically significant heme-positive urine without RBCs may be caused by the presence of either hemoglobin or myoglobin. Hemo-globinuria without hematuria can occur in the presence of acute or chronic hemolysis. Myoglobinuria without hematuria occurs in the presence of rhabdomyolysis resulting from skeletal muscle injury and is generally associated with a 5-fold increase in the plasma concentration of creatinine kinase. Rhabdomyolysis is always clinically significant as it may lead to acute renal injury. It can occur secondary to viral myositis, crush injury, severe electrolyte abnormalities (hypernatremia, hypophosphatemia), hypotension, disseminated intravascular coagulation, toxins (drugs, venom), metabolic disorders of muscles, and prolonged seizures. Clinically innocuous heme-negative urine can appear red, cola colored, or burgundy, owing to ingestion of various drugs, foods (blackberries, beets), or dyes used in food and candy, whereas dark brown (or black) urine can result from various urinary metabolites.

Evaluation of the child with hematuria begins with a careful history, physical examination, and urinalysis. This information is used to determine the level of hematuria (upper vs lower urinary tract) and to determine the urgency of the evaluation based on symptomatology. Special consideration needs to be given to family history, identification of anatomic abnormalities and malformation syndromes, presence of gross hematuria, and manifestations of hypertension, edema, or heart failure.

Table 509-2 lists causes of hematuria. Upper urinary tract sources of hematuria originate within the nephron (glomerulus, tubular system, or interstitium). Lower urinary tract sources of hematuria originate from the pelvocaliceal system, ureter, bladder, or urethra. Hematuria from within the glomerulus is often associated with brown, cola- or tea-colored, or burgundy urine, proteinuria >100 mg/dL via dipstick, urinary microscopic findings of RBC casts, and deformed urinary RBCs (particularly acanthocytes). Hematuria originating within the tubular system may be associated with the presence of leukocytes or renal tubular casts. Lower urinary tract sources of hematuria may be associated with gross hematuria that is bright red or pink, terminal hematuria (gross hematuria occurring at the end of the urine stream), blood clots, normal urinary RBC morphology, and minimal proteinuria on dipstick (<100 mg/dL).

Patients with hematuria can present with a number of symptoms suggesting specific disorders. Tea- or cola-colored urine, facial or body edema, hypertension, and oliguria are classic symptoms of glomerulonephritis. Diseases commonly manifesting as glomerulonephritis include postinfectious glomerulonephritis, immunoglobulin A (IgA) nephropathy, membranoproliferative glomerulonephritis, Henoch-Schönlein purpura (HSP) nephritis, systemic lupus erythematosus (SLE) nephritis, granulomatosis with polyangiitis (formerly Wegener granulomatosis), microscopic polyarteritis nodosa, Goodpasture syndrome, and hemolytic-uremic syndrome. A history of recent upper respiratory, skin, or gastrointestinal infection suggests postinfectious glomerulonephritis, hemolytic-uremic syndrome, or HSP nephritis. Rash and joint complaints suggest HSP or SLE nephritis.

Hematuria associated with glomerulonephritis is typically painless, but can be associated with flank pain when acute or unusually severe. Frequency, dysuria, and unexplained fevers suggest a urinary tract infection, whereas renal colic suggests nephrolithiasis. A flank mass can suggest hydronephrosis, renal cystic diseases, renal vein thrombosis, or tumor. Hematuria associated with headache, mental status changes, visual changes (diplopia), epistaxis, or heart failure suggests significant hypertension. Patients with hematuria and a history of trauma require immediate evaluation (see Chapter 72). Child abuse must always be suspected in the child presenting with unexplained perineal bruising and hematuria.

A careful family history is critical in the initial assessment of the child with hematuria given the numerous genetic causes of renal disorders. Hereditary glomerular diseases include hereditary nephritis (Alport syndrome), thin glomerular basement membrane disease, SLE nephritis, and IgA nephropathy (Berger disease). Other hereditary renal disorders with a hereditary component include both autosomal recessive and autosomal dominant polycystic kidney disease.
diseases, atypical hemolytic-uremic syndrome, urolithiasis, and sickle cell disease/trait.

A complete physical examination is critical to assess the cause of hematuria. Hypertension, edema, or signs of heart failure suggest acute glomerulonephritis. Several malformation syndromes are associated with renal disease including VATER (vertebral body anomalies, anal atresia, tracheoesophageal fistula, and renal dysplasia) syndrome. Abdominal masses may be caused by bladder distention in posterior urethral valves, hydronephrosis in ureteropelvic junction obstruction, polycystic kidney disease, or Wilms tumor. Hematuria seen in patients with neurologic or cutaneous abnormalities may be the result of a number of syndromic renal disorders including tuberous sclerosis, von Hippel-Lindau syndrome, and Zellweger (cerebrohepatorenal) syndrome. Anatomic abnormalities of the external genitalia may be associated with hematuria and/or renal disease.

Patients with gross hematuria present additional challenges because of the associated parental anxiety. The most common cause of gross hematuria is bacterial urinary tract infection. Urethrorrhagia, which is urethral bleeding in the absence of urine, is associated with dysuria and blood spots on underwear after voiding. This condition, which often occurs in prepubertal boys at intervals several months apart, has a benign self-limited course. Less than 10% of patients have evidence of glomerulonephritis. Recurrent episodes of gross hematuria suggest IgA nephropathy, Alport syndrome, or thin glomerular basement membrane disease. Dysuria and abdominal or flank pain are symptoms of idiopathic hypercalciuria, or urolithiasis. Table 509-3 lists common causes of gross hematuria; Figure 509-1 outlines a general approach to the laboratory and radiologic evaluation of the patient with glomerular or extraglomerular hematuria. Asymptomatic patients with isolated microscopic hematuria should not undergo extensive diagnostic evaluation, because such hematuria is often transient and benign.

**Figure 509-1 Algorithm of the general approach to the laboratory and radiologic evaluation of the patient with glomerular or extraglomerular hematuria.** ANA, antinuclear antibody; ASO, antistreptolysin O; BUN, blood urea nitrogen; C3/C4, complement; CBC, complete blood cell count; Cr, creatinine; RBC, red blood cell.
The child with completely asymptomatic isolated microscopic hematuria that persists on at least 3 urinalyses observed over a minimum of a 2 wk period poses a dilemma in regard to the degree of further diagnostic testing that should be performed. Significant disease of the urinary tract is uncommon with this clinical presentation. The initial evaluation of these children should include a urine culture followed by a spot urine for hypercalciuria with a calcium:creatinine ratio in culture-negative patients. In African-American patients, a sickle cell screen should be included. If these studies are normal, urinalysis of all first-degree relatives is indicated. Renal and bladder ultrasonography should be considered to rule out structural lesions such as tumor, cystic disease, hydronephrosis, or urolithiasis. Ultrasonography of the urinary tract is most informative in patients presenting with gross hematuria, abdominal pain, flank pain, or trauma. If these initial studies are normal, assessment of serum creatinine and electrolytes is recommended.

The finding of certain hematologic abnormalities can narrow the differential diagnosis. Anemia in this setting may be caused by hypervolemia with dilution associated with acute renal failure; decreased RBC production in chronic renal failure; hemolysis from hemolytic-uremic syndrome, a chronic hemolytic anemia, or SLE; blood loss from pulmonary hemorrhage, as seen in Goodpasture syndrome; or melena in patients with HSP or hemolytic-uremic syndrome. Inspection of the peripheral blood smear might reveal a microangiopathic process consistent with the hemolytic-uremic syndrome. The presence of autoantibodies in SLE can result in a positive Coombs test, the presence of antinuclear antibody, leukopenia, and multisystem disease. Thrombocytopenia can result from decreased platelet production (malignancies) or increased platelet consumption (SLE, idiopathic thrombocytopenic purpura, hemolytic-uremic syndrome, renal vein thrombosis, or congenital hepatic fibrosis with portal hypertension secondary to autosomal recessive polycystic kidney disease). Although urinary RBC morphology may be normal with lower tract bleeding and dysmorphic from glomerular bleeding, it is not sensitive enough to unequivocally delineate the site of hematuria. A bleeding diathesis is an unusual cause of hematuria. Coagulation studies are not routinely obtained unless personal or family history suggests a bleeding tendency.

A voiding cystourethrogram is only required in patients with a urinary tract infection, renal scarring, hydrourerter, or pyelocaliectasis. Cystoscopy is an unnecessary and costly procedure in most pediatric patients with hematuria, and carries the associated risks of anesthesia. The diagnosis of “possible urethral stenosis” as an indication for cystoscopy should be viewed with a high degree of suspicion, because true urethral stenosis is quite rare. This procedure should be reserved for evaluating the rare child with a bladder mass noted on ultrasound, urethral abnormalities caused by trauma, posterior urethral valves, or tumor. The finding of unilateral gross hematuria localized by cystoscopy is rare, but it can indicate a vascular malformation or another anatomic abnormality.

Children with persistent asymptomatic isolated hematuria and a completely normal evaluation should have their blood pressure and urine checked every 3 mo until the hematuria resolves. Referral to a pediatric nephrologist should be considered for patients with persistent asymptomatic hematuria greater than 1 yr duration and is recommended for patients with nephritis (glomerulonephritis, tubulo-interstitial nephritis), hypertension, renal insufficiency, urolithiasis or nephrocalcinosis, or a family history of renal disease such as polycystic kidney disease or hereditary nephritis. Renal biopsy is indicated for some children with persistent microscopic hematuria, and most children with recurrent gross hematuria associated with decreased renal function, proteinuria, or hypertension.

Bibliography is available at Expert Consult.
Bibliography
Isolated Glomerular Diseases with Recurrent Gross Hematuria
Cynthia G. Pan and Ellis D. Avner

Approximately 10% of children with gross hematuria have an acute or a chronic form of glomerulonephritis that may be associated with a systemic illness. The gross hematuria, which is usually characterized by brown or cola-colored urine, may be painless or associated with vague flank or abdominal pain. Presentation with gross hematuria is common within 1-2 days after the onset of an apparent viral upper respiratory tract infection in immunoglobulin (Ig) A nephropathy, and typically resolves within 5 days. This relatively short period contrasts to a latency period of 7-21 days occurring between the onset of a streptococcal pharyngitis or impetiginous skin infection and the development of poststreptococcal acute glomerulonephritis. Gross hematuria in these circumstances can last as long as 4-6 wk. Gross hematuria can also be seen in children with glomerular basement membrane (GBM) disorders such as hereditary nephritis (Alport syndrome [AS]) and thin GBM disease. These glomerular diseases can also manifest as microscopic hematuria and/or proteinuria without gross hematuria.

510.1 Immunoglobulin A Nephropathy (Berger Nephropathy)
Cynthia G. Pan and Ellis D. Avner

IgA nephropathy is the most common chronic glomerular disease in children. It is characterized by a predominance of IgA within mesangial glomerular deposits in the absence of systemic disease. Diagnosis requires renal biopsy, which is performed when clinical features warrant confirmation of the diagnosis or characterization of the histologic severity, which might affect therapeutic decisions.

PATHOLOGY AND PATHOLOGIC DIAGNOSIS
Focal and segmental mesangial proliferation and increased mesangial matrix are seen in the glomerulus (Fig. 510-1). Renal histology

Figure 510-1 Light microscopy of IgA nephropathy demonstrating segmental mesangial proliferation and increased matrix (×180).
hematuria episodes from of Isolated Alport kindreds. Genetic factors. Genome-wide linkage analysis suggests the linkage hypothesis that these 2 diseases are part of the same disease spectrum. Abnormalities identified in the IgA system have also been observed in patients with production of IgG and IgA autoantibodies. The abnormalities identified in the IgA system have also been observed in patients with Henoch-Schönlein purpura, and this finding lends support to the hypothesis that these 2 diseases are part of the same disease spectrum. Familial clustering of IgA nephropathy cases suggests the importance of genetic factors. Genome-wide linkage analysis suggests the linkage of IgA nephropathy to 6q22-23 in multiplex IgA nephropathy kindreds.

CLINICAL AND LABORATORY MANIFESTATIONS
IgA nephropathy is seen more often in male than in female patients. Although there are rare cases of rapidly progressive forms of the disease, the clinical presentation of childhood IgA nephropathy is often benign in comparison to that of adults. IgA nephropathy is an uncommon cause of end-stage renal failure during childhood. A majority of children with IgA nephropathy in the United States and Europe present with gross hematuria, whereas microscopic hematuria and/or proteinuria is a more common presentation in Japan. Other presentations include acute nephritic syndrome, nephrotic syndrome, or a combined nephritic-nephrotic picture. Gross hematuria often occurs within 1-2 days of onset of an upper respiratory or gastrointestinal infection, in contrast to the longer latency period observed in acute postinfectious glomerulonephritis, and may be associated with loin pain. Proteinuria is often <1000 mg/24 hr in patients with asymptomatic microscopic hematuria. Mild to moderate hypertension is most often seen in patients with nephritic or nephrotic syndrome, but is rarely severe enough to result in hypertensive emergencies. Normal serum levels of C3 in IgA nephropathy help to distinguish this disorder from post-streptococcal glomerulonephritis. Serum IgA levels have no diagnostic value because they are elevated in only 15% of pediatric patients.

PROGNOSIS AND TREATMENT
Although IgA nephropathy does not lead to significant kidney damage in most children, progressive disease develops in 20-30% of patients 15-20 yr after disease onset. Therefore, most children with IgA nephropathy do not display progressive renal dysfunction until adulthood, prompting the need for careful long-term follow-up. Poor prognostic indicators at presentation or follow-up include persistent hypertension, diminished renal function, and significant, increasing, or prolonged proteinuria. A more severe prognosis is correlated with histologic evidence of diffuse mesangial proliferation, extensive glomerular crescents, glomerulosclerosis, and diffuse tubulointerstitial changes, including inflammation and fibrosis.

The primary treatment of IgA nephropathy is appropriate blood pressure control and management of significant proteinuria. Angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists are effective in reducing proteinuria and retarding the rate of disease progression when used individually or in combination. Fish oil, which contains antiinflammatory omega-3 polyunsaturated fatty acids, may decrease the rate of disease progression in adults. If renin-angiotensin blockade proves ineffective and significant proteinuria persists, then addition of immunosuppressive therapy with corticosteroids is recommended. Corticosteroids reduce proteinuria and improve renal function in those patients with a glomerular filtration rate >60 mL/min/m². It remains unclear if the effects of glucocorticoids deter progression to end-stage renal failure to a degree to offset their significant side effects. To date, additional immunosuppression with cyclophosphamide or azathioprine has not appeared to be effective, but further randomized clinical trials are in progress. Tonsillectomy has been used as treatment for IgA nephropathy in many countries including Japan. Performing a tonsillectomy in the absence of significant tonsillitis in association with IgA nephropathy is currently not recommended until appropriate prospective, controlled trials have been performed and demonstrate efficacy. Patients with IgA nephropathy may undergo successful kidney transplantation. Although recurrent disease is frequent, allograft loss caused by IgA nephropathy occurs in only 15-30% of patients.

Bibliography is available at Expert Consult.

510.2 Alport Syndrome
Cynthia G. Pan and Ellis D. Avner

AS, or hereditary nephritis, is a genetically heterogeneous disease caused by mutations in the genes coding for type IV collagen, a major component of basement membranes. These genetic alterations are associated with marked variability in clinical presentation, natural history, and histologic abnormalities.

GENETICS
Approximately 85% of patients have X-linked inheritance caused by a mutation in the COL4A5 gene encoding the α5 chain of type IV collagen. Patients with a subtype of X-linked AS and diffuse leimyomatosis demonstrate a contiguous mutation within the COL4A5 and COL4A6 genes that encodes the α5 and α6 chains, respectively, of type IV collagen. Autosomal recessive forms of AS are caused by mutations in the COL4A3 and COL4A4 genes on chromosome 2 encoding the α3 and α4 chains, respectively, of type IV collagen. An autosomal dominant form of AS linked to the COL4A3-COL4A4 gene locus occurs in 5% of cases.

PATHOLOGY
Kidney biopsy specimens during the 1st decade of life show few changes on light microscopy. Later, the glomeruli may develop mesangial proliferation and capillary wall thickening, leading to progressive glomerular sclerosis. Tubular atrophy, interstitial inflammation and fibrosis, and lipid-containing tubular or interstitial cells, called foam cells, develop as the disease progresses. Immunopathologic studies are usually nondiagnostic.

In most patients, electron microscopy reveals diffuse thickening, thinning, splitting, and layering of the glomerular and tubular basement membranes (Fig. 510-3). To confound diagnosis, ultrastructural analysis of the GBM in all genetic forms of AS may be completely normal, display nonspecific alterations, or demonstrate only uniform thinning.

Figure 510-2 Immunofluorescence microscopy of the biopsy specimen from a child with episodes of gross hematuria demonstrating mesangial deposition of IgA (×150).
Bibliography

Although most of these patients will not carry an identified mutation. Available for families with members who have X-linked AS and who have had a pregnancy where a fetus with X-linked AS was identified in the family. A combination of careful family history, a screening urinalysis of 1st-degree relatives, an audiogram, and an ophthalmologic examination are critical in making the diagnosis of AS. The presence of anterior lenticonus is pathognomonic. AS is highly likely in the patient who has hematuria and at least 2 of the following characteristic clinical features: macular flecks, recurrent corneal erosions, GBM thickening and thinning, or sensorineural deafness. Absence of epidermal basement membrane staining for the α5 chain of type IV collagen in male hemizygotes and discontinuous epidermal basement membrane staining in female heterozygotes on skin biopsy is pathognomonic for X-linked AS and can preclude diagnostic renal biopsy. Genetic testing is clinically available for X-linked AS and COL4A5 mutations. Prenatal diagnosis is available for families with members who have X-linked AS and who carry an identified mutation.

**CLINICAL MANIFESTATIONS**

All patients with AS have asymptomatic microscopic hematuria, which may be intermittent in girls and younger boys. Single or recurrent episodes of gross hematuria commonly occurring 1-2 days after an upper respiratory infection are seen in approximately 50% of patients. Proteinurin is often seen in boys but may be absent, mild, or intermittent in girls. Progressive proteinuria, often exceeding 1 g/24 hr, is common by the 2nd decade of life and can be severe enough to cause nephrotic syndrome.

Bilateral sensorineural hearing loss, which is never congenital, develops in 90% of hemizygous males with X-linked AS, 10% of heterozygous females with X-linked AS, and 67% of patients with autosomal recessive AS. This deficit begins in the high-frequency range, but progresses to involve hearing associated with normal speech, prompting the need for hearing aids. Ocular abnormalities, which occur in 30-40% of patients with X-linked AS, include anterior lenticonus (extrusion of the central portion of the lens into the anterior chamber), macular flecks, and corneal erosions. Leiomyomatosis of the esophagus, tracheobronchial tree, and female genitals in association with platelet abnormalities has been reported, but is rare.

**DIAGNOSIS**

A combination of careful family history, a screening urinalysis of 1st-degree relatives, an audiogram, and an ophthalmologic examination are critical in making the diagnosis of AS. The presence of anterior lenticonus is pathognomonic. AS is highly likely in the patient who has hematuria and at least 2 of the following characteristic clinical features: macular flecks, recurrent corneal erosions, GBM thickening and thinning, or sensorineural deafness. Absence of epidermal basement membrane staining for the α5 chain of type IV collagen in male hemizygotes and discontinuous epidermal basement membrane staining in female heterozygotes on skin biopsy is pathognomonic for X-linked AS and can preclude diagnostic renal biopsy. Genetic testing is clinically available for X-linked AS and COL4A5 mutations. Prenatal diagnosis is available for families with members who have X-linked AS and who carry an identified mutation.

**PROGNOSIS AND TREATMENT**

The risk of progressive renal dysfunction leading to end-stage renal disease (ESRD) is highest among hemizygous and autosomal recessive homozygotes. ESRD occurs before age 30 yr in approximately 75% of hemizygotes with X-linked AS. The risk of ESRD in X-linked heterozygotes is 12% by age 40 yr and 30% by age 60 yr. Risk factors for progression are gross hematuria during childhood, nephrotic syndrome, and prominent GBM thickening. Infratal family variation in phenotypic expression results in significant differences in the age of ESRD among family members. No specific therapy is available to treat AS, although angiotensin-converting enzyme inhibitors (and possibly angiotensin-2 receptor inhibitors) can slow the rate of progression. Careful management of renal failure complications such as hypertension, anemia, and electrolyte imbalance is critical. Patients with ESRD are treated with dialysis and kidney transplantation (see Chapter 535). Approximately 5% of kidney transplantation recipients develop anti-GBM nephritis, which occurs primarily in males with X-linked AS who develop ESRD before age 30 yr.

Pharmacologic treatment of proteinuria with angiotensin-converting enzyme inhibition or angiotensin II receptor blockade has proven effective in other glomerular diseases and has also shown promise in AS. Screening of heterozygote carriers for significant renal disease in later adulthood and possible treatment of significant proteinuria is also recommended.

**510.3 Thin Basement Membrane Disease**

Cynthia G. Pan and Ellis D. Avner

Thin basement membrane disease (TBMD) is defined by the presence of persistent microscopic hematuria and isolated thinning of the GBM (and, occasionally, tubular basement membranes) on electron microscopy. Microscopic hematuria is often initially observed during childhood and may be intermittent. Episodic gross hematuria can also be present, particularly after a respiratory illness. Isolated hematuria in multiple family members without renal dysfunction is referred to as benign familial hematuria. Although most of these patients will not undergo renal biopsy, it is often presumed that the underlying pathology is TBMD. TBMD may be sporadic or transmitted as an autosomal dominant trait. Heterozygous mutations in the COL4A3 and COL4A4 genes, which encode the α3 and α4 chains of type IV collagen present in the GBM, result in TBMD. Rare cases of TBMD progress, and such patients develop significant proteinuria, hypertension, or renal insufficiency. Homozygous mutations in these same genes result in autosomal recessive AS. Therefore, in these rare cases, the absence of a positive family history for renal insufficiency or deafness would not necessarily predict a benign outcome. Consequently, monitoring patients with benign familial hematuria for progressive proteinuria, hypertension, or renal insufficiency is important through childhood and young adulthood.

Chapter 511
Glomerulonephritis Associated with Infections

511.1 Acute Poststreptococcal Glomerulonephritis
Cynthia G. Pan and Ellis D. Avner

Group A β-hemolytic streptococcal infections are common in children and can lead to the postinfectious complication of acute glomerulonephritis (GN). Acute poststreptococcal glomerulonephritis (APSGN) is a classic example of the acute nephritic syndrome characterized by the sudden onset of gross hematuria, edema, hypertension, and renal insufficiency. It is one of the most common glomerular causes of gross
hematuria in children and is a major cause of morbidity in group A β-hemolytic streptococcal infections.

**ETIOLOGY AND EPIDEMIOLOGY**

APSGN follows infection of the throat or skin by certain “nephritogenic” strains of group A β-hemolytic streptococci. Epidemics and clusters of household (camps, military) cases occur throughout the world, and 97% of cases occur in less-developed countries. The overall incidence has decreased in industrialized nations, presumably as a result of improved hygienic conditions and the near eradication of streptococcal pyoderma. Poststreptococcal GN commonly follows streptococcal pharyngitis during cold-weather months and streptococcal skin infections or pyoderma during warm-weather months. Although epidemics of nephritis have been described in association with throat (serotypes M1, M4, M25, and some strains of M12) and skin (serotype M49) infections, this disease is most commonly sporadic.

**PATHOLOGY**

Glomeruli appear enlarged and relatively bloodless and show diffuse mesangial cell proliferation, with an increase in mesangial matrix (Fig. 511-1). Polymorphonuclear leukocyte infiltration is common in glomeruli during the early stage of the disease. Crescents and interstitial inflammation may be seen in severe cases, but these changes are not specific for poststreptococcal GN. Immunofluorescence microscopy reveals a pattern of “lumpy-bumpy” deposits of immunoglobulin and complement on the glomerular basement membrane and in the mesangium. On electron microscopy, electron-dense deposits, or “humps,” are observed on the epithelial side of the glomerular basement membrane (Fig. 511-2).

**PATHOGENESIS**

Morphologic studies and a depression in the serum complement (C3) level provide strong evidence that APSGN is mediated by immune complexes. Circulating immune complex formation with streptococcal antigens and subsequent glomerular deposition is thought less likely to be a pathogenic mechanism. Molecular mimicry whereby circulating antibodies elicited by streptococcal antigens react with normal glomerular antigens, in situ immune complex formation of antistreptococcal antibodies with glomerular deposited antigen, and complement activation by directly deposited streptococcal antigens continue to be considered as probable mechanisms of immunologic injury.

Group A streptococci possess M proteins, and nephritogenic strains are related to the M protein serotype. The search for the precise nephritogenic antigen(s) that cause disease suggests that streptococcal pyogenic exotoxin (SPE) B and nephritis-associated streptococcal plasmin receptor are promising candidates. Both have been identified in glomeruli of affected patients, and in 1 study, circulating antibodies to SPE B were found in all patients. Cross-reactivity of SPE B and other M proteins with various components of the glomerular basement membrane also give evidence for molecular mimicry.

**CLINICAL MANIFESTATIONS**

Poststreptococcal GN is most common in children ages 5-12 yr and uncommon before the age of 3 yr. The typical patient develops an acute nephritic syndrome 1-2 wk after an antecedent streptococcal pharyngitis or 3-6 wk after a streptococcal pyoderma. The history of a specific infection may be absent, because symptoms may have been mild or have resolved without patients receiving specific treatment or seeking the care of a medical provider.

The severity of kidney involvement varies from asymptomatic microscopic hematuria with normal renal function to gross hematuria with acute renal failure. Depending on the severity of renal involvement, patients can develop various degrees of edema, hypertension, and oliguria. Patients are at risk for developing encephalopathy and/or heart failure secondary to hypertension or hypervolemia. Hypertensive encephalopathy must be considered in patients with blurred vision, severe headaches, altered mental status, or new seizures. The effects of acute hypertension not only depend on the severity of hypertension but also the absolute change in comparison to the patient’s baseline blood pressure and the rate at which it has risen. Respiratory distress, orthopnea, and cough may be symptoms of pulmonary edema and heart failure. Peripheral edema typically results from salt and water retention and is common; nephrotic syndrome develops in a minority (<5%) of childhood cases. Nonspecific symptoms such as malaise, lethargy, abdominal pain, or flank pain are common. Atypical presentations of APSGN include those with subclinical disease and those with severe symptoms but an absence of initial urinary abnormalities; in individuals who present with a purpuric rash, it is difficult to distinguish APSGN from Henoch-Schönlein purpura without a renal biopsy.

The acute phase generally resolves within 6-8 wk. Although urinary protein excretion and hypertension usually normalize by 4-6 wk after onset, persistent microscopic hematuria can persist for 1-2 yr after the initial presentation.

**DIAGNOSIS**

Urinalysis demonstrates red blood cells, often in association with red blood cell casts, proteinuria, and polymorphonuclear leukocytes. A
mild normochromic anemia may be present from hemodilution and low-grade hemolysis. The serum C3 level is significantly reduced in >90% of patients in the acute phase, and returns to normal 6–8 wk after onset. Although serum CH₅₀ is commonly depressed, C₄ is most often normal in APSGN, or only mildly depressed.

Confirmation of the diagnosis requires clear evidence of a prior streptococcal infection. A positive throat culture report might support the diagnosis or might represent the carrier state. A rising antibody titer to streptococcal antigen(s) confirms a recent streptococcal infection. The antistreptolysin O titer is commonly elevated after a pharyngeal infection but rarely increases after streptococcal skin infections. The best single antibody titer to document cutaneous streptococcal infection is the antideoxyribonuclease B level. If available, a positive streptozyme screen (which measures multiple antibodies to different streptococcal antigens) is a valuable diagnostic tool. Serologic evidence for streptococcal infections is more sensitive than the history of recent infections and far more sensitive than positive bacterial cultures obtained at the time of onset of acute nephritis.

Magnetic resonance imaging of the brain is indicated in patients with severe neurologic symptoms and can demonstrate posterior reversible encephalopathy syndrome in the parietooccipital areas on T2-weighted images. Chest x-ray is indicated in those with signs of heart failure or respiratory distress, or physical exam findings of a heart gallop, decreased breath sounds, rales, or hypoxemia.

The clinical diagnosis of poststreptococcal GN is quite likely in a child presenting with acute nephritic syndrome, evidence of recent streptococcal infection, and a low C3 level. However, it is important to consider other diagnoses such as systemic lupus erythematosus, endocarditis, membranoproliferative GN, and an acute exacerbation of chronic GN. Renal biopsy should be considered only in the presence of acute renal failure, nephrotic syndrome, absence of evidence of streptococcal infection, or normal complement levels. In addition, renal biopsy is considered when hematuria and proteinuria, diminished renal function, and/or a low C3 level persist more than 2 mo after onset. Persistent hypocomplementemia can indicate a chronic form of postinfectious GN or another disease such as membranoproliferative GN.

The differential diagnosis of poststreptococcal GN includes many of the causes of hematuria listed in Tables 509-2 and 511-1, and an algorithm to help with diagnosis is presented in Figure 511-3. Acute postinfectious GN can also follow other infections with coagulase-positive and coagulase-negative staphylococci, Streptococcus pneumoniae, and Gram-negative bacteria. The clinical course, histopathology, and laboratory features are similar to those described for APSGN. For some, the terms APSGN and acute postinfectious GN are used synonymously. Acute GN can occur after certain fungal, rickettsial, protozoan, parasitic, or viral diseases. Among the latter, influenza and parvovirus infections are particularly notable.

**COMPLICATIONS**

Acute complications result from hypertension and acute renal dysfunction. Hypertension is seen in 60% of patients and is associated with severe systemic symptoms, hypertension, pulmonary edema, proteinuria, and hematuria. The most common complication is acute renal failure. Poststreptococcal GN is a cause of secondary glomerulonephritis in children, with 50% of cases developing renal failure.

with hypertensive encephalopathy in 10% of cases. Although the neurologic sequelae are often reversible with appropriate management, severe prolonged hypertension can lead to intracranial bleeding. Other potential complications include heart failure, hyperkalemia, hyperphosphatemia, hypocalcemia, acidosis, seizures, and uremia. Acute renal failure can require treatment with dialysis.

**PREVENTION**

Early systemic antibiotic therapy for streptococcal throat and skin infections does not eliminate the risk of GN. Family members of patients with acute GN, especially young children, should be considered at risk and be cultured for group A β-hemolytic streptococci and treated if positive. Family pets, particularly dogs, have also been reported as carriers.

**TREATMENT**

Management is directed at treating the acute effects of renal insufficiency and hypertension (see Chapter 535.1). Although a 10 day course of systemic antibiotic therapy with penicillin is recommended to limit the spread of the nephritogenic organisms, antibiotic therapy does not affect the natural history of APSGN. This is unlike the GN seen in the context of ongoing or chronic infections, as noted in Chapter 511.2. Sodium restriction, diuresis (usually with intravenous furosemide), and pharmacotherapy with calcium channel antagonists, vasodilators, or angiotensin-converting enzyme inhibitors, are standard therapies used to treat hypertension.

**PROGNOSIS**

Complete recovery occurs in >95% of children with APSGN. Recurrences are extremely rare. Mortality in the acute stage can be avoided by appropriate management of acute renal failure, cardiac failure, and hypertension. Infrequently, the acute phase is severe and leads to glomerulosclerosis and chronic renal disease in <2% of affected children.

### 511.2 Other Chronic Infections

**Cynthia G. Pan and Ellis D. Avner**

GN is a recognized complication of various chronic infections. Classic examples include bacterial endocarditis caused by viridans streptococci and other organisms, and ventriculoperitoneal shunts infected with *Staphylococcus epidermidis*. Other infections, observed less commonly in children than in adults, include hepatitis B virus, hepatitis C virus, syphilis, and candidiasis. Parasitic infections associated with glomerulonephritis include malaria, schistosomiasis, leishmaniasis, filariasis, hydatid disease, trypanosomiasis, and toxoplasmosis. In each condition, the infecting organism has low virulence and the host is chronically infected with foreign antigen. In the presence of high levels of circulating antigen, the host's antibody response leads to formation of immune complexes that deposit in the kidneys and initiate glomerular inflammation. Foreign antigens can also stimulate an autoimmune response through the production of antibodies that cross-react with such antigens incorrectly “recognized” as glomerular structural components.

The renal histopathology can resemble poststreptococcal GN, membranous GN, or membranoproliferative GN. The clinical manifestations are generally those of an acute nephritic or nephrotic syndrome. The serum C3 and CH₅₀ complement levels are often decreased.

In HIV-associated nephropathy, direct viral infection of nephrons occurs because renal cells express a variety of lymphocyte chemokine receptors that are essential for and facilitate viral invasion. The renal expression of HIV infection is quite variable and includes an immune complex injury and a direct cytopathic effect. The classic histopathologic lesion of HIV-associated nephropathy is focal segmental glomerulosclerosis, but systemic lupus erythematosus–like glomerulonephritis, immunoglobulin A nephropathy, and membranous nephropathy have been reported. In the era of antiretroviral therapy, the decline in mortality has led to the increased recognition of renal disorders as an important complication to perinatally HIV-infected children.

Prompt eradication of any infection before severe glomerular injury occurs usually results in resolution of the GN. Progression to end-stage renal failure has been described but is uncommon. Spontaneous resolution of hepatitis B infection is common in children (30-50%) and results in remission of the glomerulopathy. Specific antivirals, interferon therapy, plasmapheresis, and immunosuppressive treatment have all been used successfully in adults with hepatitis C disease, but no controlled trials with any of these agents have been performed in pediatric patients.

Membranous Nephropathy
Scott K. Van Why and Ellis D. Avner

Membranous nephropathy (MN), amongst the most common causes of nephrotic syndrome in adults, is a rare cause of nephrotic syndrome in children. MN is classified as the primary, idiopathic form, where there is isolated renal disease, or secondary MN, where nephropathy is associated with other identifiable systemic diseases or medications. In children, secondary MN is far more common than primary, idiopathic MN. The most common etiologies of secondary MN are systemic lupus erythematosus or chronic infections. Among the latter, chronic hepatitis B infection and congenital syphilis are the best characterized and recognized causes of MN. Other chronic infections have also been associated with MN, including malaria, which is likely the most common cause of nephrotic syndrome worldwide. Certain medications, such as penicillamine and gold, or chronic factor replacement in patients with hemophilia can also cause MN. Rare causes associated with MN include tumors, such as neuroblastoma, or other idiopathic systemic diseases. Identification of secondary causes of MN is critical, because removal of the offending agent or treatment of the causative disease often leads to resolution of the associated nephropathy and improves patient outcome.

PATHOLOGY
Glomeruli have diffuse thickening of the glomerular basement membrane (GBM), without significant cell proliferative changes. Immunofluorescence and electron microscopy typically demonstrate granular deposits of immunoglobulin G and C3 located on the epithelial side of the GBM. The GBM thickening presumably results from the production of membrane-like material in response to deposition of immune complexes.

PATHOGENESIS
MN is believed to be caused by in situ immune complex formation. Therefore, antigens from the infectious agents or medications associated with secondary MN directly contribute to the pathogenesis of the renal disease. The causative antigen in idiopathic MN is not established, but the M-type phospholipase A$_2$ receptor, present on normal podocytes, may be a target antigen in idiopathic MN. Antigen from this receptor is found in immune deposits extracted from glomeruli in patients with idiopathic MN. The majority of idiopathic MN patients have circulating antibody against this podocyte membrane antigen, as well as against several podocyte cytoplasmic antigens. Childhood MN may be associated with anticationic bovine serum albumin antibodies. In addition, neutral endopeptidase antigen may be the antigen in neonatal onset MN.

CLINICAL MANIFESTATIONS
In children, MN is most common in the 2nd decade of life, but it can occur at any age, including infancy. The disease usually manifests as nephrotic syndrome and accounts for 2-6% of all cases of childhood nephrotic syndrome. Most patients also have microscopic hematuria and only rarely present with gross hematuria. Approximately 20% of children have hypertension at presentation. A subset of patients with MN present with a major venous thrombosis, commonly renal vein thrombosis. This well-known complication of nephrotic syndrome (see Chapter 527) is particularly common in patients with MN. Serum C3 and CH$_50$ levels are normal, except in cases of systemic lupus erythematosus, where levels may be depressed (see Fig. 511-3 in Chapter 511).

DIAGNOSIS
MN might be suspected on clinical grounds, particularly in the setting of known risk factors for secondary forms of the disease. The diagnosis can only be established by renal biopsy. No serologic test is specific for MN, but finding an active carrier state for hepatitis B or congenital syphilis would make the diagnosis probable in the appropriate clinical setting. Common indications for renal biopsy leading to the diagnosis of MN include presentation with nephrotic syndrome in a child >10 yr or unexplained persistent hematuria with significant proteinuria.

PROGNOSIS AND TREATMENT
The clinical course of idiopathic membranous glomerulopathy is variable. Children presenting with asymptomatic, low-grade proteinuria can enter remission spontaneously. Retrospective reports of children 1-15 yr after diagnosis, treated with a variety of regimens, indicate that 20% progress to chronic renal failure, 40% continue with active disease, and 40% achieve complete remission. Although no controlled trials have been performed in children, immunosuppressive therapy with an extended course of prednisone can be effective in promoting complete resolution of symptoms. The addition of chlorambucil or cyclophosphamide appears to provide further benefit to those not responding to steroids alone. Rituximab has shown significant promise in adults and has been proposed by some as first line treatment but has yet to be studied in a randomized controlled trial in any age group. For those unresponsive to immunosuppression, or with mild clinical features, proteinuria can be reduced with angiotensin-converting enzyme inhibitors, and by analogy, probably angiotensin-II–receptor blockers.

Bibliography
Jefferson JA, Couser WG: Membranous nephropathy in the pediatric population.

Membranoproliferative glomerulonephritis (MPGN), also known as mesangiocapillary glomerulonephritis, most commonly occurs in children or young adults. MPGN can be classified into primary (idiopathic) and secondary forms of glomerular disease. Secondary forms of MPGN are most commonly associated with subacute and chronic infection, including hepatitides B and C, syphilis, subacute bacterial endocarditis, and infected shunts, especially ventriculoatrial shunts (shunt nephritis). MPGN can also be one of the glomerular lesions seen in lupus nephritis (see Chapter 514).

**PATHOLOGY**

Primary MPGN is defined by the histologic pattern of glomeruli as seen by light, immunofluorescence, and electron microscopy. Two subtypes have been defined on histologic criteria and are associated with different clinical phenotypes. **Type I MPGN** is most common. Glomeruli have an accentuated lobular pattern from diffuse mesangial expansion, endocapillary proliferation, and an increase in mesangial cells and matrix. The glomerular capillary walls are thickened, often with splitting from interposition of the mesangium. Crescents, if present, indicate a poor prognosis. Immunofluorescence microscopy reveals C3 and lesser amounts of immunoglobulin in the mesangium and along the peripheral capillary walls in a lobular pattern. Electron
microscopy confirms numerous deposits in the mesangial and subendothelial regions.

Far less common is type II MPGN, also called dense deposit disease, which has similar light microscopic findings as type I MPGN. Differentiation from type I disease is by immunofluorescence and electron microscopy. In type II disease, C3 immunofluorescence typically is prominent, without concomitant immunoglobulin. By electron microscopy, the lamina densa in the glomerular basement membrane undergoes a very dense transformation, without evident immune complex deposits.

C3 glomerulonephritis (C3GN) is a related but separate diagnostic category. By light and electron microscopy C3GN usually has features indistinguishable from classical MPGN. Immunofluorescence studies distinguish between the two, with C3GN having only C3 deposition and MPGN having both C3 and immunoglobulin fluorescence.

**PATHOGENESIS**

Although the histology of type I MPGN produced by primary and secondary forms is indistinguishable, it appears that type I disease occurs when circulating immune complexes become trapped in the glomerular subendothelial space, which then causes injury, resulting in the characteristic proliferative response and mesangial expansion. Further evidence confirming this pathway to glomerular injury is the finding of complement activation through the classical pathway in as many as 50% of affected patients.

Type II MPGN appears not to be mediated by immune complexes. The pathogenesis of the disease is not known, but the characteristic finding of severely depressed serum complement levels suggests that deranged complement regulation might play a major role in the disease. A typical finding is markedly depressed serum C3 complement levels, with normal levels of other complement components. In many patients with type II MPGN, C3 nephritic factor (anti-C3 convertase antibody) is present. This factor activates the alternative complement pathway. In unusual cases, patients with type II MPGN demonstrate an associated systemic disease called partial lipodystrophy, where there is diffuse loss of adipose tissue and decreased complement in the presence of C3 nephritic factor. Correlation between the presence of C3 nephritic factor, complement levels, and disease presence or severity is not strong, indicating that the complement abnormalities alone are not sufficient to cause the disease.

Type II MPGN (dense deposit disease) is considered part of the broader spectrum of C3GN. The latter, as defined above pathologically, appears to be caused by primary dysregulation of the alternative or terminal cascade complement pathways.

**CLINICAL MANIFESTATIONS**

MPGN is most common in the 2nd decade of life. Systemic features may provide clues to which type of MPGN may be present, but the two histologic types of idiopathic MPGN are indistinguishable in terms of their renal manifestations. Patients present in equal proportions with nephrotic syndrome, acute nephritic syndrome (hematuria, hypertension, and some level of renal insufficiency), or persistent asymptomatic microscopic hematuria and proteinuria. Serum C3 complement levels are low in the majority of cases (see Fig. 511-3 in Chapter 511).

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis includes all forms of acute and chronic glomerulonephritis, including idiopathic and secondary forms, along with postinfectious glomerulonephritis. Postinfectious glomerulonephritis, far more common than MPGN, usually does not have nephrotic features but typically has hematuria, hypertension, renal insufficiency, and transiently low C3 complement, all features that may be seen with MPGN or C3GN. In contrast to MPGN and C3GN, where C3 levels usually remain persistently low, C3 returns to normal within 2 mo after onset of postinfectious glomerulonephritis (see Chapter 511.3). The diagnosis of MPGN is made by renal biopsy. Indications for biopsy include nephrotic syndrome in an older child, significant proteinuria with microscopic hematuria, and hypocomplementemia lasting >2 mo in a child with acute nephritis. If C3 but no immunoglobulin deposi-

**PROGNOSIS AND TREATMENT**

It is important to determine whether MPGN is idiopathic or secondary to a systemic disease, particularly lupus or chronic infection, because treatment of the causative disease can result in resolution of MPGN. Untreated, idiopathic MPGN, regardless of type, has a poor prognosis. By 10 yr following onset, 50% of patients with MPGN have progressed to end-stage renal disease. By 20 yr following onset, up to 90% have lost renal function. Those with nephrotic syndrome at the time of presentation progress to renal failure more rapidly. No definitive therapy exists, but several reports, including a randomized controlled trial, indicate that extended courses of alternate-day prednisone (for years) provide benefit. Some patients treated with steroids enter a complete clinical remission of their disease, but many have ongoing disease activity. Nevertheless, an extended course of prednisone is associated with significant preservation of renal function when compared with patients receiving no such treatment.

The prognosis of C3GN, separate from dense deposit disease (considered a part of C3GN by some) and other forms of classically defined MPGN is as yet hard to define, since reports of outcome of such patients previously had been grouped in studies of all forms of MPGN (types I and II, and even a poorly characterized type III form not considered above). The apparent pathophysiology of C3GN promises that treatments targeting the interruption of complement activation pathways, such as complement factor H replacement or shutting down the terminal complement cascade by blocking C5 activation with eculizumab (anti–C5 antibody), could be beneficial in preventing progression of renal disease.

Bibliography
Braun MC, Licht C, Strife CF: Membranoproliferative glomerulonephritis.
Systemic lupus erythematosus (SLE) is characterized by fever, weight loss, dermatitis, hematologic abnormalities, arthritis, and involvement of the heart, lungs, central nervous system, and kidneys (see Chapter 158). Glomerulonephritis is the most important cause of morbidity and mortality in SLE. Renal disease in childhood SLE is present in up to 80% of patients and is more active than that seen in adults. Occasionally, renal disease is the only presenting clinical manifestation.

**PATHOGENESIS AND PATHOLOGY**

The clinical manifestations of SLE are mediated by immune complexes. Autoantibodies are directed predominantly at nuclear antigens which act as immunogens. Binding of autoantibodies to glomerular components rather than the passive “trapping” of circulating immune complexes is central to the development of glomerulonephritis. Other pathogenic mechanisms include alterations in innate immunity that
result in amplification of inflammation. Deficiency of the complement component C1q is rare but is the strongest single genetic risk for SLE.

Kidney biopsy and evaluation of renal histopathology remain the gold standard for establishing the diagnosis of SLE nephritis and determining specific therapeutic regimens. The World Health Organization (WHO) classification of lupus nephritis is based on a combination of features including light microscopy, immunofluorescence, and electron microscopy. In patients with WHO class I nephritis (minimal mesangial lupus nephritis), no histologic abnormalities are detected on light microscopy but mesangial immune deposits are present on immunofluorescence or electron microscopy. In WHO class II nephritis (mesangial proliferative nephritis), light microscopy shows both mesangial hypercellularity and increased matrix along with mesangial deposits containing immunoglobulin and complement.

WHO class III nephritis and WHO class IV nephritis are interrelated lesions characterized by both mesangial and endocapillary lesions. Class III nephritis is defined by <50% glomeruli with involvement and class IV has ≥50% glomerular involvement. Immune deposits are present in both the mesangium and subendothelial areas. A subclassification scheme helps grade severity of the proliferative lesion based on whether the glomerular lesions are segmental (<50% glomerular tuft involved) or global (≥50% glomerular tuft involved). The WHO classification scheme also delineates whether there is a predominance of chronic disease versus active disease. Chronic injury results in glomerular sclerosis and is felt to be the consequence of significant proliferative disease seen in classes III and IV. Other signs of active disease include capillary walls that are thickened secondary to subendothelial deposits (creating the wire-loop lesion), necrosis, and crescent formation. WHO class IV nephritis is associated with poorer outcomes but can be successfully treated with aggressive immunosuppressive therapy.

WHO class V nephritis (membranous lupus nephritis) is less commonly seen as an isolated lesion and resembles idiopathic membranous nephropathy with subepithelial immune deposits. This lesion is often seen in combination with class III or IV proliferative nephritis, and if the membranous lesion is present in >50% glomeruli, both classes are noted in designation. This classification scheme also identifies cases with combinations of mixed classes III, IV, and V lesions, directing appropriate treatment for such patients. Another classification scheme by both the International Society of Nephrology and the Renal Pathology Society differs mainly in its subclassification of class IV into diffuse global and diffuse segmental lesions (Table 514-1). The value of utilizing this classification scheme, and more importantly, its impact on therapy and the results of clinical trials is unknown at this time.

Transformation of the histologic lesions of lupus nephritis from one class to another is common. This is more likely to occur among inadequately treated patients and usually results in progression to a more severe histologic lesion.

**CLINICAL MANIFESTATIONS**

The majority of children with SLE are adolescent females. Lupus nephritis affects most pediatric patients, and although commonly presenting within the first year of diagnosis, may occur at any time during the course of the disease. Ethnicity and socioeconomic factors strongly predict the development of lupus nephritis in adults with SLE but not in children. The clinical findings in patients having milder forms of lupus nephritis (all classes I-II, some class III) include hematuria, normal renal function, and proteinuria <1 g/24 hr. Some patients with class III and all patients with class IV nephritis have hematuria and proteinuria, hypertension, reduced renal function, nephrotic syndrome, or acute renal failure. The urinalysis may be normal on rare occasions in patients with proliferative lupus nephritis. Patients with class V nephritis commonly present with nephrotic syndrome.

**DIAGNOSIS**

The diagnosis of SLE is confirmed by the detection of circulating antinuclear antibodies and by demonstrating antibodies that react with native double-stranded DNA. In most patients with active disease, C3 and C4 levels are depressed. In view of the lack of a clear correlation between the clinical manifestations and the severity of the renal involvement, renal biopsy should be performed in all patients with SLE. Histopathologic findings are used to determine the selection of specific immunosuppressive therapies.

**TREATMENT**

Children with SLE should be treated by pediatric specialists in medical centers where medical and psychologic support can be provided for patients and their families. The goal of immunosuppressive therapy in lupus nephritis is to produce both a clinical remission, defined as normalization of renal function and proteinuria, and a serologic remission, defined as normalization of anti-DNA antibody, C3, and C4 levels. Therapy is initiated in all patients with prednisone at a dose of 1-2 mg/kg/day in divided doses followed by a slow steroid taper over 4-6 mo beginning 4-6 wk after achieving a serologic remission. For patients with severe forms of nephritis (WHO classes III and IV), induction therapy consists of 6 consecutive monthly intravenous infusions of cyclophosphamide at a dose of 500-1000 mg/m². Pulse intravenous methylprednisolone (1000 mg/m²) is also used in addition to oral corticosteroids. In adult clinical trials, mycophenolate mofetil was shown to be equally efficacious for induction therapy and may be considered for use in children using 600 mg/m² per dose twice daily. Maintenance therapy previously consisted of additional Cytoxan infusions every 3 mo for 18 mo, which reduced the risk of progressive renal dysfunction. Maintenance therapy using mycophenolate mofetil or azathioprine may be as efficacious as intravenous cyclophosphamide and result in less-serious side effects, such as infections, hair loss, hemorrhagic cystitis, and gonadal failure. Mycophenolate mofetil is particularly more efficacious than cyclophosphamide in African-Americans. Azathioprine, at a single daily dose of 1.5-2.0 mg/kg, may be used as a steroid-sparing agent in patients with WHO class I or II

LN, lupus nephritis.

lupus nephritis. Rituximab, a chimeric monoclonal antibody specific for human CD20, is ineffective for induction therapy for diffuse proliferative disease but may be considered in cases where resistance to conventional treatment is demonstrated. Plasmapheresis is ineffective in lupus nephritis unless there is accompanying thrombotic thrombocytopenic purpura or antineutrophilic cytoplasmic antibody–associated disease. New therapies include belimumab, a fully humanized monoclonal antibody against a type II transmembrane protein that functions in the normal survival and differentiation of B cells, which is FDA-approved for use in SLE. Its role in lupus nephritis, either in combination with current therapies or to replace them, requires extensive further study.

Hydrochloroquine is prescribed in most patients with SLE for extra-renal manifestations, but is thought to have a beneficial effect in maintaining remission in lupus nephritis. It is a rational choice given its low side effect profile. Use of antihypertensive drugs to aggressively treat hypertension as well as the specific use of drugs that block the renin–angiotensin system (angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers) to reduce proteinuria are also important therapies that appear to decrease long-term progression of renal disease.

**PROGNOSIS**

Overall, renal survival (defined as chronic kidney disease without the need for end-stage renal disease therapy) is seen in 80% of patients 10 yr after the diagnosis of SLE nephritis. Patients with diffuse proliferative WHO class IV lupus nephritis exhibit the highest risk for progression to end-stage renal disease. Concerns regarding the side effects of chronic immunosuppressive therapy and the risk of recurrent disease are lifelong. Close monitoring for relapse of disease is critical to ensure maximally successful renal outcomes. Special care must be taken to minimize the risks of infection, osteoporosis, obesity, poor growth, hypertension, and diabetes mellitus associated with chronic corticosteroid therapy. Patients require counseling regarding the risk of malignancy or infertility, which may be increased in those receiving a cumulative dose of >20 g of cyclophosphamide or other immunosuppressant therapies.

Bibliography

Henoch-Schönlein purpura (HSP) is the most common small vessel vasculitis in childhood. It is characterized by a purpuric rash and commonly accompanied by arthritis and abdominal pain (see Chapter 167.1). Approximately 50% of patients with HSP develop renal manifestations, which vary from asymptomatic microscopic hematuria to severe, progressive glomerulonephritis. The pathogenesis of HSP nephritis appears to be mediated by the deposition of polymeric immunoglobulin A (IgA) in glomeruli. This is analogous to the same type of IgA deposits seen in systemic small vessels, primarily those of the skin and intestine. The glomerular findings can be indistinguishable from those of IgA nephropathy (see Chapter 510.1). IgA deposits are present by immunofluorescence, and a broad spectrum of glomerular lesions that can range from mild proliferation to necrotic and crescentic changes can be seen.

**PATHOGENESIS AND PATHOLOGY**

The pathogenesis of HSP nephritis appears to be mediated by the deposition of polymeric immunoglobulin A (IgA) in glomeruli. This is analogous to the same type of IgA deposits seen in systemic small vessels, primarily those of the skin and intestine. The glomerular findings can be indistinguishable from those of IgA nephropathy (see Chapter 510.1). IgA deposits are present by immunofluorescence, and a broad spectrum of glomerular lesions that can range from mild proliferation to necrotic and crescentic changes can be seen.

**CLINICAL AND LABORATORY MANIFESTATIONS**

The nephritis associated with HSP usually follows onset of the rash, often presenting weeks or even months after the initial presentation of the disease. Nephritis can be manifest at initial presentation, but only rarely before onset of the rash. Patients at presentation rarely display a severe combined acute nephritic and nephrotic picture (hematuria, hypertension, renal insufficiency, significant proteinuria, and nephrotic syndrome). Most patients have only mild renal manifestations, principally isolated microscopic hematuria without significant proteinuria. Initial mild renal involvement can occasionally progress to more severe nephritis despite resolution of all other features of HSP. The severity of the systemic manifestations does not correlate with the severity of the nephritis. Most patients who develop nephritis have urinary abnormalities by 1 mo, and nearly all have abnormalities by 3 mo after onset of HSP. Therefore, a urinalysis should be performed weekly in patients with HSP during the period of active clinical disease. Thereafter, a urinalysis should be performed once a month for up to 6 mo. If all urinalyses are normal during this follow-up interval, nephritis is unlikely to develop. If proteinuria, renal insufficiency, or hypertension develops along with hematuria, consultation with a pediatric nephrologist is indicated.

**PROGNOSIS AND TREATMENT**

The prognosis of HSP nephritis for most patients is excellent. Spontaneous and complete resolution of the nephritis typically occurs in the majority of patients with mild initial manifestations (isolated hematuria with insignificant proteinuria). However, such patients uncommonly can progress to severe renal involvement, including development of chronic renal failure. Patients with acute nephritic or nephrotic syndrome at presentation have a guarded renal prognosis, particularly if they are found to have concomitant necrosis or substantial crescentic changes on renal biopsy. Untreated, the risk of developing chronic kidney disease, including renal failure, is 2-5% in all patients with HSP, but almost 50% in those with the most severe early renal clinical and histologic features.

No studies have demonstrated any efficacy of short courses (weeks) of oral corticosteroids administered promptly after onset of HSP on either preventing the development of nephritis or decreasing the severity of subsequent HSP nephritis. Tonsillectomy has been proposed as an intervention for HSP nephritis, but it also does not appear to have any measurable effect on renal outcome. Mild HSP nephritis does not require treatment, because it usually resolves spontaneously. Efficacy of treatment for moderate or severe HSP nephritis, which is far more likely to progress to chronic renal failure, is more difficult to assess. Limited prospective controlled trials for severe HSP nephritis have not shown benefit from any therapy studied. Several uncontrolled studies have reported significant benefit from aggressive immunosuppression (high-dose and extended courses of corticosteroids with cyclophosphamide or azathioprine) in patients with poor prognostic features on renal biopsy; such patients are at high risk of progressing to chronic renal failure based on historic controls. Anecdotal reports of treatment of high-risk patients with either plasmapheresis or rituximab have indicated a potential benefit. Balancing the absence of controlled data with the severe side effects of aggressive therapies in patients with poor renal prognostic factors is difficult. Aggressive therapy with careful monitoring may be reasonable in those with the most severe HSP nephritis (>50% crescents on biopsy).

Chapter 516
Rapidly Progressive (Crescentic) Glomerulonephritis
Scott K. Van Why and Ellis D. Avner

“Rapidly progressive” describes the clinical course of several forms of glomerulonephritis whose unifying feature is the histopathologic finding of crescents in the majority of glomeruli (Fig. 516-1). The terms rapidly progressive glomerulonephritis (RPGN) and crescentic glomerulonephritis (CGN) are synonymous. The natural history of most forms of CGN is rapid and relentless progression to end-stage renal failure.

CLASSIFICATION
CGN can be a severe manifestation of essentially every defined primary and secondary glomerulonephritis (GN), but particular forms of GN are more likely to present as, or evolve into, RPGN (Table 516-1). If no underlying cause is identified by systemic features, serologic testing, or histologic examination, the disease is classified as idiopathic CGN. The incidence of specific etiologies of CGN in children varies widely; certain common themes are shared in all such reports. Patients with systemic vasculitis appear to be particularly prone to develop CGN. Patients with Henoch-Schönlein purpura (HSP), antineutrophil cytoplasmic antibody (ANCA)–mediated GN (microscopic polyangiitis and granulomatosis with polyangiitis), and systemic lupus erythematosus account for the majority of patients with CGN. Postinfectious GN or endocarditis rarely progresses to CGN, but because it is the most common form of GN in childhood it accounts for a significant percentage of patients with CGN in most reports. Membranoproliferative GN and idiopathic disease make up most of the remaining cases of CGN. Immunoglobulin (Ig) A nephropathy, a common GN, only rarely is rapidly progressive. Goodpasture disease often has rapidly progressive GN as a component of the syndrome, but its rarity in childhood results in its making up only a small percentage of children with CGN.

PATHOLOGY AND PATHOGENESIS
The hallmark of CGN is the histopathologic finding of crescents in glomeruli (see Fig. 516-1). Crescent formation, through proliferation of parietal epithelial cells in Bowman's space, may be the final pathway of any severe inflammatory glomerular injury. Podocytes and renal progenitor cells are involved in the pathogenesis of CGN. Fibrous crescents, in which proliferative cellular crescents are replaced by collagen, are a late finding. The immunofluorescence findings, as well as the pattern of any deposits by electron microscopy can delineate the underlying glomerulopathy in CGN secondary to lupus, HSP nephritis, membranoproliferative glomerulonephritis, postinfectious GN, IgA nephropathy, or Goodpasture disease. Rare or absent findings by immunofluorescence and electron microscopy typify pauciimmune GN (Wegener disease and microscopic polyangiitis) and idiopathic crescentic GN.

CLINICAL MANIFESTATIONS
Most children present with acute nephritis (hematuria, some degree of renal insufficiency, and hypertension) and usually have concomitant proteinuria, often with nephrotic syndrome. Occasional patients present late in the course of disease with oliguric renal failure. Extrarenal manifestations, such as pulmonary involvement, joint symptoms, or skin lesions, can help lead to the diagnosis of the underlying systemic disease causing the CGN.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS
The diagnosis of CGN is made by biopsy. Delineation of the underlying etiology is reached by a combination of additional biopsy findings (described earlier), extrarenal symptoms and signs, and serologic testing, including evaluation of antinuclear and anti-DNA antibodies, serum complement levels, and ANCA. If the patient has no extrarenal manifestations and a negative serologic evaluation, and if the biopsy has no immune or electron microscopy deposits, the diagnosis is idiopathic, rapidly progressive CGN.

PROGNOSIS AND TREATMENT
Although the outcome is not uniformly positive, children with crescentic postinfectious GN can spontaneously recover. The natural course of CGN is far more severe in the setting of other etiologies, including the idiopathic category, and progression to end-stage renal failure within weeks to months from onset is common. Having a majority of fibrous crescents on a renal biopsy portends a poor prognosis, because the disease usually has progressed to irreversible injury. Although there are few controlled data, the consensus of most nephrologists is that the combination of high-dose corticosteroids and cyclophosphamide may be effective in preventing progressive renal failure in patients with systemic lupus erythematosus, HSP nephritis, Wegener granulomatosis, and IgA nephropathy if given early in the course when acute cellular crescents predominate. Although such therapy can also be effective in the other diseases causing RPGN, renal outcomes in those settings are less favorable. Progression to end-stage renal disease often occurs despite aggressive immunosuppressive therapy. In combination with immunosuppression, plasmapheresis has been reported to

benefit patients with Goodpasture disease. Plasmapheresis may also benefit patients with ANCA-associated CGN, in particular those with the most severe renal dysfunction at presentation. The possible benefits of plasmapheresis in other forms of RPGN are unclear.

Bibliography

Goodpasture disease is characterized by pulmonary hemorrhage and glomerulonephritis. The disease results from attack on these organs by antibodies directed against certain epitopes of type IV collagen, located within the alveolar basement membrane in the lung and glomerular basement membrane (GBM) in the kidney. The production of pathologic autoantibody against specific domains in type IV collagen is triggered by an acquired conformational change in $\alpha_3\beta_4\gamma_1$ hexamers, central structural elements in type IV collagen. The resulting structural alteration reveals neoepitopes that become the target of the pathogenic Goodpasture autoantibody.

**PATHOLOGY**
Kidney biopsy shows crescentic glomerulonephritis in most patients. Immunofluorescence microscopy demonstrates continuous linear deposition of immunoglobulin G along the GBM (Fig. 517-1).

**CLINICAL MANIFESTATIONS**
Goodpasture disease is rare in childhood. Patients usually present with hemoptysis from pulmonary hemorrhage that can be life-threatening. Concomitant renal manifestations include acute glomerulonephritis with hematuria, proteinuria, and hypertension, which usually follows a rapidly progressive course. Renal failure commonly develops within days to weeks of clinical presentation. Uncommonly, patients can have anti-GBM nephritis manifesting as isolated, rapidly progressive glomerulonephritis without pulmonary hemorrhage. In essentially all cases, serum anti-GBM antibody is present and complement C3 level is normal. Antineutrophilic cytoplasmic antibody levels can be found to be elevated along with the anti-GBM antibody; such patients doubly positive for these autoantibodies, who have severe disease at presentation, appear to have a more severe prognosis.

**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS**
The diagnosis is made by a combination of the clinical presentation of pulmonary hemorrhage with acute glomerulonephritis, the presence of serum antibodies directed against GBM (anti-type IV collagen in GBM), and characteristic renal biopsy findings. Other diseases that cause a pulmonary-renal syndrome need to be considered and include systemic lupus erythematosus, Henoch-Schönlein purpura, granulomatosis with polyangiitis, nephrotic syndrome–associated pulmonary embolism, and microscopic polyangiitis. These diseases are ruled out by the absence of other characteristic clinical features, kidney biopsy findings, and negative serologic studies for antibodies against nuclear (antinuclear antibody), DNA (anti-dsDNA), and neutrophil cytoplasmic components (antineutrophilic cytoplasmic antibody).

**PROGNOSIS AND TREATMENT**
Untreated, the prognosis of Goodpasture disease is poor. The combination of high-dose intravenous methylprednisolone, cyclophosphamide, and plasmapheresis appears to improve survival. Nevertheless, patients who survive the pulmonary hemorrhage often progress to end-stage renal failure despite ongoing immunosuppressive therapy.

Bibliography

Hemolytic-uremic syndrome (HUS) is a common cause of community-acquired acute kidney injury in young children. It is characterized by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency. HUS has clinical features in common with thrombotic thrombocytopenic purpura (TTP) (see Chapter 484.5). The etiology and pathophysiology of the more common forms of HUS clearly delineate childhood HUS as separate from idiopathic TTP.

ETIOLOGY

The various etiologies of HUS and other related thrombotic microangiopathies allow classification into infection-induced, genetic, medication-induced, and HUS associated with systemic diseases characterized by microvascular injury (Tables 518-1 and 518-2). The most common form of HUS is caused by toxin-producing *Escherichia coli* that causes prodromal acute enteritis and is commonly termed diarrhea-associated HUS. In the subcontinent of Asia and in southern Africa, the toxin of *Shigella dysenteriae* type 1 is causative, whereas in Western countries, verotoxin or Shiga-like toxin producing *E. coli* (STEC) is the usual cause.

Several serotypes of *E. coli* can produce the toxin; O157:H7 is most common in Europe and the Americas. A large epidemic of HUS in Europe was caused by Shiga toxin–producing *E. coli* O104:H4. The reservoir of STEC is the intestinal tract of domestic animals, usually cows. Disease commonly is transmitted by undercooked meat or unpasteurized (raw) milk and apple cider. Local outbreaks have followed ingestion of undercooked, contaminated hamburger or other foods cross-contaminated on unwashed cutting boards at fast food restaurants; contaminated municipal water supplies; petting farms; and swimming in contaminated ponds, lakes, or pools. With broad food distribution, wider epidemics have been traced to lettuce, raw spinach, and bean sprouts contaminated with STEC. Less often, STEC has been spread by person-to-person contact within families or child care centers. A rare but distinct entity of infection-triggered HUS is related
HUS can be superimposed on any disease associated with microvascular injury, including malignant hypertension, systemic lupus erythematosus, and antiphospholipid syndrome (see Chapter 484.4). It can also occur following bone marrow or solid organ transplantation, and may be triggered by the use of the calcineurin inhibitors cyclosporine and tacrolimus in that setting. Several other medications also can induce HUS (see Table 518-1).

**PATHOLOGY**

Kidney biopsies are only rarely performed in HUS because the diagnosis is usually established by clinical criteria and the risks of biopsy are significant during the active phase of the disease. Early glomerular changes include thickening of the capillary walls caused by swelling of endothelial cells and accumulation of fibrillar material between endothelial cells and the underlying basement membrane, causing narrowing of the capillary lumens. Platelet–fibrin thrombi are often seen in glomerular capillaries. Thrombi are also seen in afferent arterioles and small arteries with fibrinoid necrosis of the arterial wall, leading to renal cortical necrosis from vascular occlusion. Late findings include glomerular sclerosis and obsolescence secondary to either severe direct glomerular involvement or glomerular ischemia from arteriolar involvement.

**PATHOGENESIS**

Microvascular injury with endothelial cell damage is characteristic of all forms of HUS. In the diarrhea-associated form of HUS, enteropathogenic organisms produce either Shiga toxin or the highly homologous Shiga-like verotoxin both of which directly cause endothelial cell damage. Shiga toxin can directly activate platelets to promote their aggregation. In pneumococcal-associated HUS, neuraminidase cleaves sialic acid on membranes of endothelial cells, red cells, and platelets to reveal the underlying cryptic Thomsen-Friedenreich (T) antigen. Endogenous immunoglobulin M (IgM) recognizes the T antigen and triggers the microvascular angiothrombosis.

The familial recessive and dominant forms of HUS, including the inherited deficiencies of ADAMTS13 and regulators of the complement cascade, probably predispose patients to developing HUS but do not cause the disease per se, because these patients might not develop HUS until later childhood or even adulthood. In such cases, HUS is often triggered by an inciting event such as an infectious disease. The absence of ADAMTS13 impairs cleavage of von Willebrand factor multimers, which enhances platelet aggregation. Factor H plays a central role in complement regulation, primarily arresting amplification and propagation of complement activation. It is possible that mild endothelial injury that would normally resolve instead evolves to an aggressive microangiopathy because of the inherited deficiencies of these factors.

In each form of HUS, capillary and arteriolar endothelial injury in the kidney leads to localized thrombosis, particularly in glomeruli, causing a direct decrease in glomerular filtration. Progressive platelet aggregation in the areas of microvascular injury results in consumptive thrombocytopenia. Microangiopathic hemolytic anemia results from mechanical damage to red blood cells as they pass through the damaged and thrombotic microvasculature.

**CLINICAL MANIFESTATIONS**

HUS is most common in preschool and school-age children, but it can occur in adolescents and adults. In HUS caused by toxigenic E. coli, onset of HUS occurs a few days after onset of gastroenteritis with fever, vomiting, abdominal pain, and diarrhea. The prodromal intestinal symptoms may be severe and require hospitalization, but they can also be relatively mild and considered trivial. The diarrhea is often bloody, but not necessarily so. Following the prodromal illness, the sudden onset of pallor, irritability, weakness, and lethargy heralds the onset of HUS. Oliguria can be present in early stages but may be masked by ongoing diarrhea, because the prodromal enteritis often overlaps the onset of HUS, particularly with ingestion of large doses of toxin. Thus, patients with HUS can present with either significant dehydration or volume overload, depending on whether the enteritis or renal
insufficiency from HUS predominates, and the amount of fluid that has been administered.

 Patients with pneumococci-associated HUS usually are ill with pneumonia, empyema, and bacteremia when they develop HUS. Onset can be insidious in patients with the genetic forms of HUS, with HUS triggered by a variety of illnesses, including mild, nonspecific gastroenteritis or respiratory tract infections.

 HUS can be relatively mild, or can progress to a severe and fatal multisystem disease. Leukocytosis, severe prodomal enteritis, hypotension, and antibiotic use portend a severe course, but no presenting features reliably predict the severity of HUS in any given patient. Patients with HUS who appear mildly affected at presentation can rapidly develop severe, multisystem, life-threatening complications. Renal insufficiency can be mild but also can rapidly evolve into severe oliguric or anuric renal failure. The combination of rapidly developing renal failure and severe hemolysis can result in life-threatening hyperkalemia. Volume overload, hypertension, and severe anemia can all develop soon after onset of HUS, and together can precipitate heart failure. Direct cardiac involvement is rare, but pericarditis, myocardial dysfunction, or arrhythmias can occur without precipitating features of hypertension, volume overload, or electrolyte abnormalities.

 The majority of patients with HUS have some central nervous system (CNS) involvement. Most have mild manifestations, with significant irritability, lethargy, or nonspecific encephalopathic features. Severe CNS involvement occurs in ≤20% of cases. Seizures and significant encephalopathy are the most common manifestations in those with severe CNS involvement, resulting from focal ischemia secondary to microvascular CNS thrombosis. Small infarctions in the basal ganglion and cerebral cortex have also been reported, but large strokes and cerebral hemorrhage are rare. Hypertension may produce an encephalopathy and seizures. Intestinal complications can be protein and include severe inflammatory colitis, ischemic enteritis, bowel perforation, intussusception, and pancreatitis. Patients can develop petechiae, but significant or severe bleeding is rare despite very low platelet counts.

### DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis is made by the combination of microangiopathic hemolytic anemia with schistocytes, thrombocytopenia, and some degree of kidney involvement. The anemia can be mild at presentation, but rapidly progresses. Thrombocytopenia is an invariably finding in the acute phase, with platelet counts usually 20,000–100,000/mm³. Partial thromboplastin and prothrombin times are usually normal. The Coombs test is negative, with the exception of pneumococci-induced HUS, where the Coombs test is usually positive. Leukocytosis is often present and significant. Urinalysis typically shows microscopic hematuria and low-grade proteinuria. The renal insufficiency can vary from mild elevations in serum blood urea nitrogen and creatinine to acute, anuric kidney failure.

The etiology of HUS is often clear with the presence of a diarrheal prodrome or pneumococcal infection. The presence or absence of toxicogenic organisms on stool culture has little role in making the diagnosis of diarrhea-associated, enteropathic HUS. Only a minority of patients infected with those organisms develops HUS, and the organisms that cause HUS may be rapidly cleared. Therefore, the stool culture is often negative in patients who have diarrhea-associated HUS. If no history of diarrheal prodrome or pneumococcal infection is obtained, then evaluation for genetic forms of HUS should be considered, because those patients are at risk for recurrence, have a severe prognosis, and can benefit from different therapy. Other causes of acute kidney injury associated with a microangiopathic hemolytic anemia and thrombocytopenia should be considered and excluded, such as systemic lupus erythematosus, malignant hypertension, and bilateral renal vein thrombosis (see Table 518-1). A kidney biopsy is rarely indicated to diagnose HUS.

### PROGNOSIS AND TREATMENT

With early recognition and intensive supportive care, the mortality for diarrhea-associated HUS is <5% in most major medical centers. Up to half of patients may require dialysis support during the acute phase of the disease. Most recover renal function completely, but of surviving patients, 5% remain dependent on dialysis, and up to 30% are left with some degree of chronic renal insufficiency. The prognosis for HUS not associated with diarrhea is more severe. Pneumococci-associated HUS causes increased patient morbidity, with mortality reported as 20%. The familial, genetic forms of HUS can be insidiously progressive or relapsing diseases and have a poor prognosis (see Table

*Remission was defined as either complete remission or partial remission (i.e., hematologic remission with renal sequelae).
†The long-term outcome was defined as the outcome 5-10 yr after onset.
‡Patients in this category were eligible for combined liver and kidney transplantation.
§Patients in this category were eligible for single kidney transplantation.
#ESRD, end-stage renal disease.

Identification of specific factor deficiencies in some of these genetic forms provides opportunity for directed therapy to improve outcome.

The primary approach that has substantially improved acute outcome in HUS is early recognition of the disease, monitoring for potential complications, and meticulous supportive care. Supportive care includes careful management of fluid and electrolytes, including prompt correction of volume deficit, control of hypertension, and early institution of dialysis if the patient becomes significantly oliguric or anuric, particularly with hyperkalemia. Early intravenous volume expansion before the onset of oligo anuria may be nephroprotective in diarrhea-associated HUS. Red cell transfusions are usually required as hemolysis can be brisk and recurrent until the active phase of the disease has resolved. In pneumococci-associated HUS, it is critical that any administered red cells be washed before transfusion to remove residual plasma, because endogenous IgM directed against the revealed T antigen can play a role in accelerating the pathogenesis of the disease. Platelets should generally not be administered, regardless of platelet count, to patients with HUS because they are rapidly consumed by the active coagulation and theoretically can worsen the clinical course. Despite low platelet counts, serious bleeding is very rare in patients with HUS.

There is no evidence that any therapy directed at arresting the disease process of the most common, diarrhea-associated form of HUS provides benefit, and some can cause harm. Attempts have been made using anticoagulants, antiplatelet agents, fibrinolytic therapy, plasma therapy, immune globulin, and antibiotics. Anticoagulation, antiplatelet, and fibrinolytic therapies are specifically contraindicated because they increase the risk of serious hemorrhage. Antibiotic therapy to clear enteric toxigenic organisms (STEC) can result in increased toxin release, potentially exacerbating the disease, and therefore is not recommended. However, prompt treatment of causative pneumococcal infection is important. The European experience with *E. coli* O104:H4 in adults who were treated with azithromycin demonstrated more rapid elimination of the organism. Furthermore, in vitro evidence suggests that meropenem, rifaximin, and azithromycin downregulate the release and expression of Shiga toxin. Nonetheless in children with *E. coli* O157:H7–associated HUS, antibiotics are considered contraindicated.

Plasma infusion or plasmapheresis has been proposed for patients suffering severe manifestations of HUS with serious CNS involvement. There are no controlled data demonstrating the effectiveness of this approach, and it is specifically contraindicated in those with pneumococcal-associated HUS as it could exacerbate the disease. The use of plasma therapy in STEC-HUS was one of many treatment strategies during one of the largest reported outbreaks of STEC-HUS, which occurred in Europe in 2011. This outbreak was caused by an uncommon serotype (O104:H4) that had unique virulence factors. Thought initially to cause more severe disease, it differed epidemiologically from other STEC-HUS serotypes by affecting primarily healthy adults, rather than the usual pattern of affecting children and the elderly. Treatment in this epidemic included plasma exchange in most of the adult patients, as well as the use of eculizumab.

Eculizumab is an anti-C5 antibody that inhibits complement activation, a pathway that contributes to active disease in some forms of atypical familial HUS; this pathway may contribute to the process in STEC-HUS. Eculizumab is FDA approved for the treatment of atypical HUS. Because of the risk of meningococcal disease in patients with congenital defects in terminal complement components, it is recommended to give the meningococcal vaccine prior to giving eculizumab (if the patient has not been primarily immunized). While initial reports suggested that eculizumab provided benefit in patients with diarrhea-associated HUS, subsequent systematic analysis showed no benefit from either plasma exchange or eculizumab.

Plasma therapy can be of substantial benefit to patients with identified deficits of ADAMTS13 or factor H. It may also be considered in patients with other genetic forms of HUS, such as the undefined familial (recessive or dominant) form or sporadic but recurrent HUS. In contrast to its use in STEC-HUS, eculizumab shows great promise in treatment of atypical HUS, including HUS occurring following renal transplantation. Whether it should be combined with plasma therapy, or used as a primary treatment of atypical HUS, is still undetermined.

Most patients with diarrhea-associated HUS recover completely with little risk of long-term sequelae. Patients with hypertension, any level of renal insufficiency, or residual urinary abnormalities persisting a year after an episode of diarrhea–positive HUS (particularly significant proteinuria) require careful follow-up. Patients who have recovered completely with no residual urinary abnormalities after a yr are unlikely to manifest long-term sequelae. Because of some reports of late sequelae in such patients, annual examinations with a primary physician are still warranted.

519.6 Vascular Abnormalities

Craig C. Porter and Ellis D. Avner

Hemangiomas, hemangiolymphangiomas, angiomyomas, and arteriovenous malformations of the kidneys and lower urinary tract are rare causes of hematuria. They can present clinically with microscopic hematuria or gross hematuria with clots. When associated cutaneous vascular malformations are present, they can offer a clue to these underlying causes of hematuria. Renal colic can develop with any upper tract vascular abnormality that obstructs urinary drainage, induces an inflammatory response, or distends the renal capsule. The diagnosis may be confirmed by angiography or endoscopy.

Unilateral bleeding of varicose veins of the left ureter, resulting from compression of the left renal vein between the aorta and superior mesenteric artery (mesoaortic compression), is referred to as the nutcracker syndrome. Patients with this syndrome typically present with
persistent microscopic hematuria (and occasionally, recurrent gross hematuria) that may be accompanied by proteinuria, left lower abdominal pain, left flank pain, or orthostatic hypotension. Diagnosis requires a high degree of suspicion and is confirmed by Doppler ultrasonography, CT, phlebography of the left renal vein, or magnetic resonance angiography.

519.7 Renal Vein Thrombosis
Craig C. Porter and Ellis D. Avner

EPIDEMIOLOGY
Renal vein thrombosis (RVT) occurs in 2 distinct clinical settings: (1) in newborns and infants, RVT is commonly associated with asphyxia, dehydration, shock, sepsis, congenital hypercoagulable states, and maternal diabetes; and (2) in older children, RVT is seen in patients with nephrotic syndrome, cyanotic heart disease, inherited hypercoagulable states, sepsis, following kidney transplantation, and following exposure to angiographic contrast agents.

PATHOGENESIS
RVT begins in the intrarenal venous circulation and can then extend to the main renal vein and even the inferior vena cava. Thrombus formation is mediated by endothelial cell injury resulting from hypoxia, endotoxin, or contrast media. Other contributing factors include hypercoagulability from either nephrotic syndrome or mutations in genes that encode clotting factors (i.e., factor V Leiden deficiency); hypovolemia and decreased venous blood flow associated with septic shock, dehydration, or nephrotic syndrome; and intravascular sludging caused by polycythemia.

CLINICAL MANIFESTATIONS
The development of RVT is classically heralded by the sudden onset of gross hematuria and unilateral or bilateral flank masses. However, patients can also present with any combination of microscopic hematuria, flank pain, hypertension, or a microangiopathic hemolytic anemia with thrombocytopenia or oliguria. RVT is usually unilateral. Bilateral RVT results in acute kidney failure.

DIAGNOSIS
The diagnosis of RVT is suggested by the development of hematuria and flank masses in patients seen in the high-risk clinical settings or with the predisposing clinical features noted above. Ultrasonography shows marked renal enlargement, and radionuclide studies reveal little or no renal function in the affected kidney(s). Doppler flow studies of the inferior vena cava and renal vein confirm the diagnosis. Contrast studies should be avoided to minimize the risk of further vascular damage.

DIFFERENTIAL DIAGNOSIS
The differential diagnosis of RVT includes other causes of hematuria that are associated with rapid development of microangiopathic hemolytic anemia or enlargement of the kidney(s). These include hemolytic-uremic syndrome, hydronephrosis, polycystic kidney disease, Wilms tumor, and intrarenal abscess or hematoma. All patients should be evaluated for congenital and acquired hypercoagulable states.

TREATMENT
The primary treatment of RVT starts with aggressive supportive intensive care, including correction of fluid and electrolyte imbalance and treatment of renal insufficiency. The American College of Chest Physicians recommends that the additional initial treatment of bilateral RVT should include tissue plasminogen activator and unfractionated heparin followed by continued anticoagulation with unfractionated or low-molecular-weight heparin. Treatment recommendations for unilateral RVT with inferior vena cava extension include either unfractionated or low-molecular-weight heparin. There is no consensus as to whether unilateral RVT without extension should be managed with heparin or with supportive therapy alone. Aggressive treatment with thrombolytic agents in all of these clinical settings, as well as antithrombotic prevention of patients with documented thrombotic risk, remains controversial despite such recommendations given the significant risks of bleeding. Evidence-based data, particularly in children, do not exist despite such “best-practice” recommendations. Children with severe hypertension secondary to RVT who are refractory to antihypertensive medications may require nephrectomy.

PROGNOSIS
Perinatal mortality from RVT has decreased significantly over the past 20 yr. Partial or complete renal atrophy is a common sequela of RVT in the neonate, leading to an increased risk of renal insufficiency, renal tubular dysfunction, and systemic hypertension. These complications are also seen in older children. However, recovery of renal function is not uncommon in older children with RVT resulting from nephrotic syndrome or cyanotic heart disease with correction of the underlying etiology.

Bibliography is available at Expert Consult.

519.8 Idiopathic Hypercalciuria
Craig C. Porter and Ellis D. Avner

Idiopathic hypercalciuria, which may be inherited as an autosomal dominant disorder, can clinically present as recurrent gross hematuria, persistent microscopic hematuria, dysuria, or abdominal pain in the absence of stone formation. Hypercalciuria can also accompany conditions resulting in hypercalcemia, such as hyperparathyroidism, vitamin D intoxication, immobilization, and sarcoidosis. Hypercalciuria may be associated with Cushing syndrome, corticosteroid therapy, tubular dysfunction secondary to Fanconi syndrome (Wilson disease, oculocerebrorenal syndrome), Williams syndrome, distal renal tubular acidosis, or Bartter syndrome (see Chapter 531). Hypercalciuria may also be seen in patients with Dent disease, which is an X-linked form of nephrolithiasis associated with hypophosphatemic rickets. Although microcrystal formation with consequent tissue irritation is believed to mediate symptoms, the precise mechanism by which hypercalciuria causes hematuria or dysuria is unknown.

DIAGNOSIS
Hypercalciuria is diagnosed by a 24 hr urinary calcium excretion >4 mg/kg. A screening test for hypercalciuria may be performed on a random urine specimen by measuring the calcium and creatinine concentrations. A spot urine calcium:creatinine ratio (mg/dL:mg/dL) >0.2 suggests hypercalciuria in an older child. Normal ratios may be as high as 0.8 in infants <7 mo of age.

TREATMENT
Left untreated, hypercalciuria leads to nephrolithiasis in approximately 15% of cases. Hypercalciuria has also been associated with an increased risk for development of low bone mineral density as well as an increased incidence of urinary tract infections. Idiopathic hypercalciuria has been identified as a risk factor in 40% of children with kidney stones, and a low urinary citrate level has been associated as a risk factor in approxi mately 38% of this group. Oral thiazide diuretics can normalize urinary calcium excretion by stimulating calcium reabsorption in the proximal and distal tubules. Such therapy can lead to resolution of gross hematuria or dysuria and can prevent nephrolithiasis. The precise indications for thiazide treatment (including its duration if initiated) remain controversial.

In patients with persistent gross hematuria or dysuria, therapy is initiated with hydrochlorothiazide at a dose of 1-2 mg/kg/24 hr as a single morning dose. The dose is titrated upward until the 24 hr urinary calcium excretion is <4 mg/kg and clinical manifestations
Bibliography
**Bibliography**

resolve. After 1 yr of treatment, hydrochlorothiazide is usually discontinued, but may be resumed if gross hematuria, nephrolithiasis, or dysuria recurs. During hydrochlorothiazide therapy, the serum potassium level should be monitored periodically to avoid hypokalemia. **Potassium citrate** at a dose of 1 mEq/kg/24 hr may also be beneficial, particularly in patients with low urinary citrate excretion and symptomatic dysuria.

Sodium restriction is important because urinary calcium excretion parallels sodium excretion. Importantly, *dietary calcium restriction is not recommended* (except in children with massive calcium intake >250% of recommended dietary allowance by dietary history) because calcium is a critical requirement for growth, and no evidence supports a relationship between decreased calcium intake and decreased urinary calcium levels. This is particularly important given the association of hypercalciuria in some patients with reduced bone mineral density. A number of uncontrolled, small-scale studies support a role for bisphosphonate therapy, which leads to a reduction in urinary calcium excretion and improvement in bone mineral density. Controlled studies are necessary to establish a clear role for such therapy in children with hypercalciuria.

Hematologic Diseases Causing Hematuria

520.1 Sickle Cell Nephropathy
Craig C. Porter and Ellis D. Avner

Gross or microscopic hematuria may be seen in children with sickle cell disease or sickle trait. Hematuria tends to resolve spontaneously in the majority of children (see Chapters 462.1 and 462.2). With the exception of an association with renal cell carcinoma, clinically apparent renal involvement occurs more commonly in patients with sickle cell disease than in those with sickle cell trait.

ETIOLOGY
The renal manifestations of sickle cell nephropathy (SSN) are generally related to microthrombosis secondary to sickling in the relatively hypoxic, acidic, hypertonic renal medulla where vascular stasis is present. Analgesic use, volume depletion with consequent prerenal failure, infection, and iron-related hepatic disease are independent contributing factors. Glomerular hyperfiltration, mediated by the intrarenal production of prostaglandins and synthesis of nitric oxide, is involved in the pathogenesis of proteinuria and kidney failure in SSN.

PATHOLOGY
Ischemia, papillary necrosis, and interstitial fibrosis are common pathologic findings in SSN. The specific sickle cell glomerular lesion consists of glomerular hypertrophy, with glomerulomegaly and distended capillaries. In addition, a variety of glomerular lesions are also found in SSN; most commonly these include focal segmental glomerulosclerosis, membranoproliferative glomerulonephritis, and thrombotic microangiopathy. The pathophysiology of these specific glomerulonephritic lesions in SSN is poorly understood but is probably associated with the same factors that produce idiopathic or secondary disease as previously described (see Chapters 511-513).

CLINICAL MANIFESTATIONS
Clinical manifestations of SSN include polyuria caused by a urinary concentrating defect, renal tubular acidosis, and proteinuria associated with the glomerular lesions noted above. Approximately 20-30% of patients with sickle cell disease develop proteinuria. Nephrotic-range proteinuria with or without clinically apparent nephrotic syndrome occurs in up to 30% of patients with SSN, and when present generally heralds progressive renal failure.

TREATMENT
Tubular manifestations have no specific treatment other than those recommended generally for patients with sickle cell disease. However, angiotensin-converting enzyme inhibitors and/or angiotensin II receptor inhibitors can be used to effect a significant reduction in urine protein excretion in patients with daily urine protein excretion exceeding 500 mg, and may slow progression of renal failure. Gross hematuria secondary to papillary necrosis may respond to treatment with ε-aminocaproic acid or desmopressin acetate. Hydroxyurea and newer treatments for sickle cell disease (see Chapter 462.1) have decreased the manifestations of SSN in proportion to the other complications of the primary hemoglobinopathy.

PROGNOSIS
SSN can eventually lead to hypertension, renal insufficiency, and progressive kidney failure. Dialysis and eventual kidney transplantation are successful treatment modalities when kidney failure is irreversible.

Bibliography is available at Expert Consult.

520.2 Coagulopathies and Thrombocytopenia
Craig C. Porter and Ellis D. Avner

Gross or microscopic hematuria may be associated with inherited or acquired disorders of coagulation (hemophilia, disseminated intravascular coagulation, thrombocytopenia). In these cases, however, hematuria is not usually the presenting complaint or a major factor affecting clinical management of outcome (see Chapters 475-484).
**Bibliography**

Chapter 521

Anatomic Abnormalities Associated with Hematuria

521.1 Congenital Anomalies

Gross or microscopic hematuria may be associated with many different types of malformations of the urinary tract. The sudden onset of gross hematuria after minor trauma to the flank is often associated with ureteropelvic junction obstruction, cystic kidneys, or enlarged kidneys from any cause (see Chapter 537).
521.2 Autosomal Recessive Polycystic Kidney Disease
Craig C. Porter and Ellis D. Avner

Also previously referred to as infantile polycystic disease, autosomal recessive polycystic kidney disease (ARPKD) is an autosomal recessive disorder occurring with an incidence of 1:10,000 to 1:40,000, and a gene carrier rate in the general population of 1/70. The gene for ARPKD (PKHD1 [polycystic kidney and hepatic disease]) encodes fibrocystin, a large protein (>4,000 amino acids) with multiple isoforms.

PATHOLOGY
Both kidneys are markedly enlarged and grossly show innumerable cysts throughout the cortex and medulla. Microscopic studies demonstrate dilated, ectatic collecting ducts radiating from the medulla to the cortex, although transient proximal tubule cysts have been reported in the fetus. Development of progressive interstitial fibrosis and tubular atrophy during advanced stages of disease eventually leads to renal failure. ARPKD causes dual-organ disease and should be considered as ARPKD/congenital hepatic fibrosis. Liver involvement is characterized by a basic ductal plate abnormality that leads to bile duct proliferation and ectasia, as well as progressive hepatic fibrosis.

PATHOGENESIS
Fibrocystin may form a multimeric complex with proteins of other primary genetic cystic diseases. It appears that altered intracellular signaling from these complexes, located at epithelial apical cell surfaces, intercellular junctions, and basolateral cell surfaces in association with the focal adhesion complex, is a critical feature of disease pathophysiology. A large number of mutations in PKHD1 (without identified specific "hot spots") cause disease, and the same mutation can give variable degrees of disease severity in the same family. This clinical observation is consistent with preclinical data demonstrating many environmental and unknown genetic factors affecting disease expression. The false-negative rate for genetic diagnosis is approximately 10%. Limited available information suggests only gross genotype-phenotype correlation: mutations that modify fibrocystin appear to cause less-severe disease than those that truncate fibrocystin.

CLINICAL MANIFESTATIONS
The typical child presents with bilateral flank masses during the neonatal period or in early infancy. ARPKD may be associated with oligohydramnios, pulmonary hypoplasia, respiratory distress, and spontaneous pneumothorax in the neonatal period. Perinatal demise (approximately 25-30%) appears to be associated with truncating mutations. Components of the oligohydramnios complex (Potter syndrome), including low-set ears, micrognathia, flattened nose, limb-positioning defects, and intrauterine growth restriction, may be present at death from pulmonary hypoplasia. Hypertension is usually noted within the first few weeks of life, is often severe, and requires aggressive multidrug therapy for control. Oliguria and acute renal failure are uncommon, but transient hyponatremia, often in the presence of acute renal failure, often responds to diuresis. Renal function is usually impaired but may be initially normal in 20-30% of patients. Approximately 50% of patients with a neonatal-perinatal presentation develop end-stage renal disease (ESRD) by age 10 yr.

ARPKD is increasingly recognized in infants (and, rarely, in adolescents and young adults) with a mixed renal-hepatic clinical picture. Such children and young adults often present with predominantly hepatic manifestations in combination with variable degrees of renal disease. Hepatic disease manifests as portal hypertension, hepatosplenomegaly, gastrointestinal varices, episodes of ascending cholangitis, prominent cutaneous periumbilical veins, reversal of portal vein flow, and thrombocytopenia. Renal findings in patients with a hepatic presentation may range from asymptomatic renal ultrasound to systemic hypertension and renal insufficiency. In the newborn, clinical evidence of liver disease by radiologic or clinical laboratory assessment is present in approximately 45% of children and believed to be universal by microscopic evaluation. Natural history studies of ARPKD patients presenting as infants and young children have classified this group in terms of the severity of their dual-organ phenotype: 40% severe renal/severe kidney and 20% of each of the following—severe kidney/mild liver, severe liver/mild kidney, and mild kidney/mild liver.

DIAGNOSIS
The diagnosis of ARPKD is strongly suggested by bilateral palpable flank masses in an infant with pulmonary hypoplasia, oligohydramnios, and hypertension and the absence of renal cysts by sonography of the parents (Fig. 521-1). Markedly enlarged and uniformly hyperchogenic kidneys with poor corticomедullary differentiation are commonly seen on ultrasonography (Fig. 521-2). The diagnosis is supported by clinical and laboratory signs of hepatic fibrosis, pathologic findings of ductal plate abnormalities seen on liver biopsy, anatomic and pathologic proof of ARPKD in a sibling, or parental consanguinity. The diagnosis can be confirmed by genetic testing. The differential diagnosis includes other causes of bilateral renal enlargement and/or cysts, such as multicystic dysplasia, hydronephrosis, Wilms tumor, and bilateral renal vein thrombosis (Tables 521-1 and 521-2).

Nephronophthisis, an autosomal recessive disorder with renal fibrosis, tubular atrophy, and cyst formation is a common cause of ESRD in children and adolescents (Tables 521-1 and 521-2). Associated external findings include retinal degeneration (Senior-Loken syndrome), cerebellar ataxia (Joubert syndrome), and hepatic fibrosis (Boichis disease). Symptoms include polyuria (salt wasting, poor concentrating ability), failure to thrive, and anemia. Hypertension and edema are seen later when ESRD develops. Prenatal diagnostic testing using genetic linkage analysis or direct mutation analysis is available in families with a previously affected child.

Preimplantation genetic diagnosis with in vitro fertilization may avoid the birth of another affected child with ARPKD.

TREATMENT
The current treatment of ARPKD is supportive. Aggressive ventilatory support is often necessary in the neonatal period secondary to pulmonary hypoplasia, hypoventilation, and the respiratory illnesses of prematurity. Careful management of hypertension (angiotensin-converting enzyme inhibitors), fluid and electrolyte abnormalities, osteopenia, and clinical manifestations of renal insufficiency is essential. Children with severe respiratory failure or feeding intolerance from enlarged kidneys can require unilateral or, more commonly, bilateral nephrectomies, prompting the need for renal replacement therapy. For many children approaching ESRD therapy, significant portal hypertension is present. This in combination with the dramatic improvement in liver transplantation survival has led to consideration of dual renal and hepatic transplantation in a carefully selected group of patients. Dual transplantation thus avoids the later development of end-stage liver disease despite successful renal transplantation.

PROGNOSIS
Mortality has improved dramatically, although approximately 30% of patients die in the neonatal period from complications of pulmonary hypoplasia. Neonatal respiratory support and renal replacement therapies have increased the 10 yr survival of children surviving beyond the 1st yr of life to >80%. Fifteen-year survival is currently estimated at 70-80%. Consideration of dual renal and hepatic transplantation and the development of disease-specific therapies for pediatric clinical trials will further positively impact the natural history of ARPKD. An important resource for families of patients is the ARPKD/CHF Alliance (www.arpkdchf.org).

NPHP, Nephronophthisis. CHF, congenital hepatic fibrosis.

Autosomal dominant polycystic kidney disease (ADPKD) is the most common hereditary human kidney disease, with an incidence of 1/400 to 1/1,000. It is a systemic disorder with possible cyst formation in multiple organs (liver, pancreas, spleen, brain) and the development of saccular cerebral aneurysms.

**PATHOLOGY**
Both kidneys are enlarged and show cortical and medullary cysts originating from all regions of the nephron.

**PATHOGENESIS**
Approximately 85% of patients with ADPKD have mutations that map to the PKD1 gene on the short arm of chromosome 16, which encodes polycystin, a transmembrane glycoprotein. Another 10-15% of ADPKD mutations map to the PKD2 gene on the long arm of chromosome 4, which encodes polycystin 2, a proposed nonselective cation channel.
The majority of mutations appear to be unique to a given family. At present, a mutation can be found in 85% of patients with well-characterized disease. Approximately 8-10% of patients will have de novo, disease-causing mutations. Mutations of PKD1 are associated with more severe renal disease than mutations of PKD2. The pathophysiology of the disease appears to be related to disruption of normal multimeric cystoprotein complexes, with consequent abnormal intracellular signaling resulting in abnormal proliferation, tubular secretion, and cyst formation. Abnormal growth factor expression, coupled with low intracellular calcium and elevated cyclic adenosine monophosphate, appear to be important features leading to formation of cysts and progressive enlargement.

**Clinical Presentation**

The severity of renal disease and the clinical manifestations of ADPKD are highly variable. Although symptomatic ADPKD commonly occurs in the 4th or 5th decade of life, symptoms, including gross or microscopic hematuria, bilateral flank pain, abdominal masses, hypertension, and urinary tract infection, may be seen in neonates, children, and adolescents. With the increased utilization of abdominal sonography in the pediatric population, as well as ADPKD families now requesting possible screening in their asymptomatic, at-risk offspring (with the passage of the Genetic Information Nondiscrimination Act in the United States), most children with ADPKD are diagnosed by abnormal renal sonography in the absence of symptoms. Renal ultrasonography usually demonstrates multiple bilateral macrocysts in enlarged kidneys (Fig. 521-3), although normal kidney size and unilateral disease may be seen in the early phase of the disease in children.

ADPKD is a multiorgan disorder affecting many tissue types. Cysts may be asymptomatic but present within the liver, pancreas, spleen, and ovaries and when present help confirm the diagnosis in childhood. Intracranial aneurysms, which appear to segregate within certain families, have an overall prevalence of 15% and are an important cause of mortality in adults, but occasionally occur in children. Mitral valve prolapse is seen in approximately 12% of children; aortic and coronary artery aneurysms and aortic valve insufficiency are noted in affected adults. Hernias, bronchiectasis, and intestinal diverticula can also occur in these children.

**Diagnosis**

ADPKD is confirmed by the presence of enlarged kidneys with bilateral macrocysts in a patient with an affected 1st-degree relative. De novo mutations occur in 8-10% of patients with newly diagnosed disease. The diagnosis might be made in children before their affected parent, making parental renal sonography an important diagnostic test to be performed in families with no apparent family history. Among patients with genetically defined ADPKD, screening renal ultrasonography results may be normal in ≤50% by 20 yr of age and <3% by 30 yr of age.

Prenatal diagnosis is suggested from the presence of enlarged kidneys with or without cysts on ultrasonography in families with known ADPKD. Prenatal DNA testing is available in families with affected members whose disease is caused by identified mutations in the PKD1 or PKD2 genes.

The differential diagnosis includes renal cysts associated with glomerulocystic kidney disease, tuberous sclerosis, and von Hippel-Lindau disease, which may be inherited in an autosomal dominant pattern (see Table 521-1). The neonatal manifestations of ADPKD and ARPKD may rarely be indistinguishable.

**Treatment and Prognosis**

Treatment of ADPKD is primarily supportive. Control of blood pressure is critical because the rate of disease progression in ADPKD correlates with the presence of hypertension. Angiotensin-converting enzyme inhibitors and/or angiotensin II receptor antagonists are agents of choice. Obesity, caffeine ingestion, smoking, multiple pregnancies, male gender, and possibly the use of calcium channel blockers appear to accelerate disease progression. Older patients with a family history of intracranial aneurysm rupture should be screened for cerebral aneurysms.

Although neonatal ADPKD may be fatal, long-term survival of the patient and the kidneys is possible for children surviving the neonatal period. ADPKD that occurs initially in older children has a favorable prognosis, with normal renal function during childhood seen in >80% of children.

Although disease-specific therapy is not yet available, a number of clinical trials are in progress based on promising preclinical laboratory investigation (www.clinicaltrials.gov). A valuable resource for patients and their families is the Polycystic Kidney Disease Foundation (www.pkdcure.org).

### 521.4 Trauma

Craig C. Porter and Ellis D. Avner

Infants and children are more susceptible to renal injury following blunt or penetrating injury to the back or abdomen because of their...
Bibliography
decreased muscle mass “protecting” the kidney. Gross or microscopic hematuria, flank pain, and abdominal rigidity can occur; associated injuries may be present (see Chapter 72). In the absence of hemodynamic instability, most renal trauma can be managed nonoperatively. Urethral trauma can result from crush injury, often associated with a fractured pelvis or from direct injury. Such injury is suspected in the appropriate clinical setting when gross blood appears at the external urethral meatus. Rhabdomyolysis and consequent renal failure is another complication of crush injury that can be ameliorated by vigorous fluid resuscitation. There may be a relationship between microscopic hematuria and recreational accidents in individuals >16 yr of age, none of whom exhibited hypotension or required surgical intervention.

Bibliography
hematuria associated with viral hemorrhagic cystitis usually resolves within 1 wk.

Bibliography is available at Expert Consult.

522.3 Vigorous Exercise

Priya Pais and Ellis D. Avner

Gross or microscopic hematuria can follow vigorous exercise. Exercise hematuria is less common in females and can be associated with dysuria. Approximately 30-60% of runners completing marathons have dipstick-positive urine for blood. In limited follow-up, none appeared to have any significant urinary tract abnormalities. The color of the urine following vigorous exercise can vary from red to black. Blood clots may be rarely present in the urine. Findings on urine culture, intravenous pyelography, voiding cystourethrography, and cystoscopy are normal in most patients. This seems to be a benign condition, and the hematuria generally resolves within 48 hr after cessation of exercise. The absence of red blood cell casts or evidence of renal disease and the presence of dysuria and blood clots in some patients suggest that the source of bleeding lies in the lower urinary tract. Rhabdomyolysis with myoglobinuria or hemoglobinuria must be considered in the differential diagnosis when associated with symptoms in the appropriate clinical context. Hydronephrosis or anatomic abnormalities must be considered in any child who presents with hematuria (particularly gross) after mild exercise or following mild trauma. Appropriate imaging studies are indicated in this setting.

Bibliography
NORMAL PHYSIOLOGY
The charge and size selective properties of the glomerular capillary wall prevent significant amounts of albumin, globulin, and other large plasma proteins from entering the urinary space (see Chapter 508). Smaller proteins (low-molecular-weight proteins) do cross the capillary wall but are reabsorbed by the proximal tubule. A very small amount of protein that normally appears in the urine is the result of normal tubular secretion. The normally excreted protein mostly consists of Tamm-Horsfall protein (uromodulin), a protective glycoprotein secreted by the tubules that inactivates cytokines.

PATHOPHYSIOLOGY OF PROTEINURIA
Abnormal amounts of protein may appear in the urine from 3 possible mechanisms: glomerular proteinuria, which occurs as a result of
disruption of the glomerular capillary wall; tubular proteinuria, a tubular injury or dysfunction that leads to ineffective reabsorption of mostly low-molecular-weight proteins; and increased production of plasma proteins—in multiple myeloma, rhabdomyolysis, or hemolysis—which may cause the production or release of very large amounts of protein that are filtered at the glomerulus and overwhelm the absorptive capacity of the proximal tubule.

**MEASUREMENT OF URINE PROTEIN**

Urine protein can be measured in random collected samples or in timed (e.g., 24 hr or overnight) samples. Tests to accurately quantify urine protein concentration rely on precipitation with sulfosalicylic acid and measurement of turbidity (Table 523-1).

### Urine Dipstick Measurement of Protein

Total protein concentration in urine can be estimated with chemically impregnated plastic strips that contain a pH-sensitive colorimetric indicator that changes color when negatively charged proteins, such as albumin, bind to it. Dipsticks primarily detect albuminuria and are less sensitive for other forms of proteins (low-molecular-weight proteins, Bence Jones protein, gamma globulins). Visual changes in the color of the dipstick are a semiquantitative measure of urinary protein concentration. The dipstick is reported as negative, trace (10-29 mg/dL), 1+ (30-100 mg/dL), 2+ (100-300 mg/dL), 3+ (300-1000 mg/dL), and 4+ (>1000 mg/dL). False-positive results can occur with a very high urine pH (>7.0), a highly concentrated urine specimen, or contamination of the urine with blood. False-negative test results can occur in patients with dilute urine or a large volume of urine output or in disease states in which the predominant urinary protein is not albumin.

Positive urine dipstick test for protein is considered to be present if there is more than a trace (10-29 mg/dL) in a urine sample in which the specific gravity is <1.010. If the specific gravity is >1.015, the dipstick must read ≥1+ (>30 mg/dL) to be considered clinically significant.

Because the dipstick reaction offers only a qualitative measurement of urinary protein excretion, children with persistent proteinuria should have proteinuria quantitated more precisely. **Timed (24 hr) urine collections** offer more precise information regarding urinary protein excretion than a randomly performed dipstick test. Urinary protein excretion in the normal child is less than 100 mg/m²/day or a total of 150 mg/day. In neonates, normal urinary protein excretion is higher, up to 300 mg/m², because of reduced reabsorption of filtered proteins. A reasonable upper limit of normal protein excretion in healthy children is 150 mg/24 hr. More specifically, normal protein excretion in children is defined as ≤4 mg/m²/hr; abnormal proteinuria is defined as excretion of 4-40 mg/m²/hr; and nephrotic-range proteinuria is defined as >40 mg/m²/hr.

Timed urine collections are cumbersome to obtain, and the sensitivity and specificity of the test can be influenced by fluid intake, the volume of urine output, and the importance of including a complete collection without missed voids.

### Urine Protein-to-Creatinine Ratio Measurement

Urine protein-to-creatinine ratio measurement of an untimed (spot) urine specimen has largely replaced timed urine collection. In children, urine protein-to-creatinine ratios have been shown to significantly correlate with measurements of 24 hr urine protein and are useful to screen for proteinuria and to longitudinally monitor urine protein levels.

This ratio is calculated by dividing the urine protein concentration (mg/dL) by the urine creatinine concentration (mg/dL) to provide a simple measure. It should be ideally performed on a first morning voided urine specimen to eliminate the possibility of orthostatic (postural) proteinuria (see Chapter 525). A ratio of <0.5 in children <2 yr of age and <0.2 in children >2 yr of age suggests normal urinary protein excretion. A ratio greater than 2 suggests nephrotic-range proteinuria.

**CLINICAL CONSIDERATIONS**

The finding of proteinuria in children and adolescents in a single, non–first morning urine specimen is common, varying between 5% and 15%. The prevalence of persistent proteinuria on repeated testing is much less common. The challenge is to differentiate the child with proteinuria related to renal disease from the otherwise healthy child with transient or other benign forms of proteinuria. When proteinuria is detected it is important to determine if it is transient, orthostatic, or fixed in nature.

**Microalbuminuria** is defined as the presence of albumin in the urine above the normal level but below the detectable range of conventional urine dipstick methods. In adults, persistent microalbuminuria (defined as a urinary albumin excretion of 30-300 mg/g creatinine on at least 2-3 samples) is accepted as evidence of diabetic nephropathy and also a predictor of cardiovascular and renal disease. The mean level of urinary albumin excretion falls between 8 and 10 mg/g of creatinine in children >6 yr of age. Similar to adults, microalbuminuria in children has been found to be associated with obesity and to predict, with reasonable specificity, the development of diabetic nephropathy in type 1 diabetes mellitus.

*Note that in a 24 hr urine specimen, the creatinine content should be measured to determine whether the specimen is truly a 24 hr collection. The amount of creatinine in a 24 hr specimen can be estimated as follows: females, 15-20 mg/kg; males, 20-25 mg/kg. Adapted from Hogg RJ, Portman RJ, Milliner D, et al, Evaluation and management of proteinuria and nephrotic syndrome in children: recommendations from a Pediatric Nephrology Panel Established at the National Kidney Foundation Conference on Proteinuria, Albuminuria, Risk Assessment, Detection, and Elimination (PARADE), Pediatrics 105(6):1242–1249, 2000.
Bibliography
The majority of children found to have positive tests for protein on urinary dipsticks will have negative evaluations on repeated dipsticks and normal urinary protein if formally quantitated. Approximately 10% of children who undergo random urinalysis have proteinuria by a single dipstick measurement. Across the school-age spectrum, this finding occurs more commonly in adolescents than in younger children. In most cases, serial testing of the patient's urine demonstrates resolution of the abnormality. This phenomenon defines transient proteinuria, and its cause remains elusive. Defined contributing factors include a temperature >38.3°C (101°F), exercise, dehydration, cold exposure, heart failure, seizures, or stress. Transient proteinuria usually does not exceed 1-2+ on the dipstick. No evaluation or therapy is needed for children with this benign condition. Persistence of proteinuria, even if low grade, is not consistent with the diagnosis and suggests the need for additional evaluation.

Bibliography is available at Expert Consult.
**Bibliography**
Orthostatic proteinuria is the most common cause of persistent proteinuria in school-age children and adolescents, occurring in up to 60% of children with persistent proteinuria. Children with this condition are usually asymptomatic, and the condition is discovered by routine urinalysis. Patients with orthostatic proteinuria excrete normal or minimally increased amounts of protein in the supine position. In the upright position, urinary protein excretion may be increased 10-fold, up to 1,000 mg/24 hr (1 g/24 hr). Hematuria, hypertension, hypoalbuminemia, edema, and renal dysfunction are absent.

In a child with persistent asymptomatic proteinuria, the initial evaluation should include an assessment for orthostatic proteinuria. It begins with the collection of a first morning urine sample, with subsequent testing of any urinary abnormalities by a complete urinalysis and determination of a spot protein : creatinine (Pr : Cr) ratio. The correct collection of the first morning urine sample is critical. The child must fully empty the bladder before going to bed and then collect the first voided urine sample immediately upon arising in the morning. The absence of proteinuria (dipstick negative or trace for protein; and a normal ratio of urinary protein [mg/dL] to urinary creatinine [mg/dL] = [uPr/uCr] <0.2) on the first morning urine sample for 3 consecutive days confirms the diagnosis of orthostatic proteinuria. No further evaluation is necessary, and the patient and family should be reassured of the benign nature of this condition. However, if there are other abnormalities of the urinalysis (e.g., hematuria), or if the urine uPr : uCr ratio is >0.2, the patient should be referred to a pediatric nephrologist for a complete evaluation.

The cause of orthostatic proteinuria is unknown, although altered renal hemodynamics and partial left renal vein obstruction in the upright, lordotic position have been proposed as possible causes.

Increased body mass index is recognized as a strong correlate of orthostatic proteinuria. Long-term follow-up studies in young adults suggest that orthostatic proteinuria is a benign process, but similar data are not available for children. Therefore, long-term follow-up of children is prudent. Patients should be monitored for the development of nonorthostatic proteinuria, particularly in the presence of hematuria, hypertension, or edema. Such findings may herald underlying kidney disease.

Bibliography is available at Expert Consult.
Bibliography

Children found to have fixed proteinuria on a first morning urine sample on 3 separate occasions should be further investigated. Fixed proteinuria is defined as a first morning urine sample that is ≥1+ on dipstick testing with a urine specific gravity >1.015 or with a protein-to-creatinine ratio of ≥0.2. Fixed proteinuria indicates a potential kidney disease caused by either glomerular or tubular disorders.

526.1 Glomerular Proteinuria

The glomerular capillary wall consists of 3 layers: the fenestrated capillary endothelium, the glomerular basement membrane, and the podocytes (with foot processes and intercalated slit diaphragms) (Fig. 526-1). Glomerular proteinuria results from alterations in the permeability of any of the layers of the glomerular capillary wall to normally filtered proteins and occurs in a variety of renal diseases (Table 526-1). Glomerular proteinuria can range widely from <1 g to >30 g of protein in a 24 hr period. The podocyte is the predominant cell of injury in most glomerular diseases characterized by heavy proteinuria.

Glomerular proteinuria should be suspected in any patient with a first morning urine protein : creatinine ratio >1.0, or significant proteinuria of any degree, accompanied by hypertension, hematuria, edema, or renal dysfunction (elevated blood urea nitrogen, creatinine). Disorders characterized primarily by proteinuria include idiopathic (minimal change) nephrotic syndrome, focal segmental glomerulosclerosis, mesangial proliferative glomerulonephritis, membranous nephropathy, membranoproliferative glomerulonephritis, diabetic nephropathy, and obesity-related glomerulopathy. Other renal disorders that can include proteinuria as a prominent feature include acute postinfectious glomerulonephritis, immunoglobulin A nephropathy, lupus nephritis, Henoch-Schönlein purpura nephritis, and Alport syndrome.

Initial evaluation of a child with fixed proteinuria should include measurement of serum creatinine and electrolyte panel, first morning urine protein : creatinine ratio, serum albumin level, and complement levels. The child should be referred to a pediatric nephrologist for further evaluation and management. Renal biopsy is often necessary to establish a diagnosis and guide therapy.

In asymptomatic patients with low-grade proteinuria (protein : creatinine ratio between 0.2 and 1.0) in whom all other findings are normal, renal biopsy might not be indicated because the underlying process may be transient or resolving or because specific pathologic features of a chronic kidney disease might not yet be apparent. Such patients should have periodic reevaluation (ideally every 4-6 mo unless the patient is symptomatic). The evaluation should consist of a physical examination with accurate blood pressure measurement, urinalysis, measurement of serum creatinine and a repeat first morning urine
Figure 526-1 Glomerular capillary wall. The 3 layers of the capillary wall (glomerular endothelial cell, glomerular basement membrane [GBM], and podocyte) act as the glomerular filtration barrier (GFB), preventing proteins and large molecules from passing from the capillary lumen into the urinary space. The podocyte cell body lies within the urinary space, and the cell is attached to the GBM through foot processes. Adjacent foot processes are separated by the filtration slit, bridged by the slit diaphragm. Disruption of the GFB leads to the passage of protein across the capillary wall, leading to proteinuria. (From Jefferson JA, Nelson PJ, Najafian B, Shankland SJ. Podocyte disorders: core curriculum 2011. Am J Kidney Dis 58:666–677, 2011, Fig 1.)

526.2 Tubular Proteinuria

Priya Pais and Ellis D. Avner

A variety of renal disorders that primarily involve the tubulointerstitial compartment of the kidney can cause low-grade fixed proteinuria (protein:creatinine ratio 0.2:1.0). In the healthy state, large amounts of proteins of lower molecular weight than albumin are filtered by the glomerulus and reabsorbed in the proximal tubule. Injury to the proximal tubules can result in diminished reabsorptive capacity and the loss of these low-molecular-weight proteins in the urine.

Tubular proteinuria (see Table 526-1) may be seen in acquired and inherited disorders and may be associated with other defects of proximal tubular function, such as the Fanconi syndrome (glycosuria, phosphaturia, bicarbonate wasting, and aminoaciduria). Tubular proteinuria is a consistent finding among patients with the X-linked tubular syndrome, Dent disease, caused by mutations of the renal chloride channel.

Asymptomatic patients having persistent proteinuria generally have glomerular rather than tubular proteinuria. In occult cases, glomerular and tubular proteinuria can be distinguished by electrophoresis of the urine. In tubular proteinuria, little or no albumin is detected, whereas in glomerular proteinuria, the major protein is albumin.

Bibliography

Bibliography

Nephrotic syndrome is the clinical manifestation of glomerular diseases associated with heavy (nephrotic-range) proteinuria. Nephrotic-range proteinuria is defined as proteinuria >3.5 g/24 hr or a urine protein:creatinine ratio >2. The triad of clinical findings associated with nephrotic syndrome arising from the large urinary losses of protein are hypoalbuminemia (≤2.5 g/dL), edema, and hyperlipidemia (cholesterol >200 mg/dL).

Nephrotic syndrome affects 1-3 per 100,000 children <16 yr of age. Without treatment, nephrotic syndrome in children is associated with a high risk of death, most commonly from infections. Fortunately, 80% of children with nephrotic syndrome respond to corticosteroid therapy. Although glucocorticoid therapy is standard therapy for nephrotic syndrome, neither the target cell nor the mechanism of action of steroids has been determined. Early referral to a pediatric nephrologist is recommended for initial management of nephrotic syndrome. However, continued care of these children is always a collaborative effort between the nephrologist and the primary care physician.

ETIOLOGY
Most children with nephrotic syndrome have a form of primary or idiopathic nephrotic syndrome (Table 527-1). Glomerular lesions associated with idiopathic nephrotic syndrome include minimal change disease (the most common), focal segmental glomerulosclerosis, membranoproliferative glomerulonephritis, C3 glomerulopathy, and membranous nephropathy (Table 527-2). These etiologies have different age distributions (Fig. 527-1). Nephrotic syndrome may also be secondary to systemic diseases such as systemic lupus erythematosus, Henoch-Schönlein purpura, malignancy (lymphoma and leukemia), and infections (hepatitis, HIV, and malaria) (see Table 527-1). A number of hereditary proteinuria syndromes are caused by mutations in genes that encode critical protein components of the glomerular filtration apparatus (Table 527-3).

PATHOGENESIS
Role of the Podocyte
The underlying abnormality in nephrotic syndrome is an increased permeability of the glomerular capillary wall, which leads to massive proteinuria and hypoalbuminemia. The podocyte plays a crucial role in the development of proteinuria and progression of glomerulosclerosis. The podocyte is a highly differentiated epithelial cell located on the outside of the glomerular capillary loop (see Chapter 508.1). Foot processes are extensions of the podocyte that terminate on the glomerular basement membrane. The foot processes of a podocyte interdigitate with those from adjacent podocytes and are connected by a slit called the slit diaphragm. The podocyte functions as structural support of the capillary loop, is a major component of the glomerular filtration barrier to proteins, and is involved in synthesis and repair of the glomerular basement membrane. The slit diaphragm is one of the major impediments to protein permeability across the glomerular capillary wall. Slit diaphragms are not simple passive filters—they consist of numerous proteins that contribute to complex signaling pathways and play an important role in podocyte function. Important component proteins of the slit diaphragm include nephrin, podocin, CD2AP, and α-actinin 4. Podocyte injury or genetic mutations of genes producing podocyte proteins may cause nephrotic-range proteinuria (see Table 527-3).

In idiopathic, hereditary, and secondary forms of nephrotic syndrome, there are immune and nonimmune insults to the podocyte that lead to foot process effacement of the podocyte, a decrease in number of functional podocytes, and altered slit diaphragm integrity. The end result is increased protein “leakiness” across the glomerular capillary wall into the urinary space.

Role of the Immune System
Minimal change nephrotic syndrome (MCNS) may occur after viral infections and allergen challenges. MCNS has also been found to occur in children with Hodgkin lymphoma and T-cell lymphoma. That immunosuppression occurs with drugs such as corticosteroids and cyclosporine provides indirect additional evidence that the immune system contributes to the overall pathogenesis of the nephrotic syndrome.

CLINICAL CONSEQUENCES OF NEPHROTIC SYNDROME
Edema
Edema is the most common presenting symptom of children with nephrotic syndrome. Despite its almost universal presence, there is uncertainty as to the exact mechanism of edema formation. There are 2 opposing theories, the underfill hypothesis and the overfill hypothesis, that have been proposed as mechanisms causing nephrotic edema.

The underfill hypothesis is based on the fact that nephrotic-range proteinuria leads to a fall in the plasma protein level with a corresponding decrease in intravascular oncotic pressure. This leads to leakage of plasma water into the interstitium, generating edema. As a result of reduced intravascular volume, there is increased secretion of vasopressin and atrial natriuretic factor, which, along with aldosterone, result in increased sodium and water retention by the tubules. Sodium and water retention therefore occur as a consequence of intravascular volume depletion.

This hypothesis does not fit the clinical picture of some patients with edema caused by nephrotic syndrome who have clinical signs of intravascular volume overload, not volume depletion. Treating these patients with albumin alone may not be sufficient to induce a diuresis.
without the concomitant use of diuretics. Also, reducing the renin–aldosterone axis with mineralocorticoid receptor antagonists does not result in a marked increase in sodium excretion. With the onset of remission of MCNS, many children will have increased urine output before their urinary protein excretion is measurably reduced.

The overfill hypothesis postulates that nephrotic syndrome is associated with primary sodium retention, with subsequent volume expansion and leakage of excess fluid into the interstitium. There is accumulating evidence that the epithelial sodium channel in the distal tubule may play a key role in sodium reabsorption in nephrotic syndrome. The clinical weaknesses of this hypothesis are evidenced by the numerous nephrotic patients who present with an obvious clinical picture of intravascular volume depletion: low blood pressure, tachycardia, and elevated hemocentration. Furthermore, amiloride, an epithelial sodium channel blocker, used alone is not sufficient to induce adequate diuresis.

The goal of therapy should be a gradual reduction of edema with judicious use of diuretics, sodium restriction, and cautious use of intravenous albumin infusions, if indicated.

**Hyperlipidemia**

There are several alterations in the lipid profile in children with nephrotic syndrome, including an increase in cholesterol, triglycerides, low-density lipoprotein, and very-low-density lipoproteins. The high-density lipoprotein level remains unchanged or is low. In adults, this results in an increase in the adverse cardiovascular risk ratio, although the implications for children are not as serious, especially those with steroid-responsive nephrotic syndrome. Hyperlipidemia is thought to be the result of increased synthesis as well as decreased catabolism of lipids. Although commonplace in adults, the use of lipid-lowering agents in children is uncommon.

**Increased Susceptibility to Infections**

Children with nephrotic syndrome are especially susceptible to infections such as cellulitis, spontaneous bacterial peritonitis, and bacteremia. This occurs as a result of many factors, particularly hypoglobulinemia as a result of the urinary losses of immunoglobulin (Ig) G. In addition, defects in the complement cascade from urinary loss of complement factors (predominantly C3 and C5), as well as alternative pathway factors B and D, lead to impaired opsonization of microorganisms. Children with nephrotic syndrome are at significantly increased risk for infection with encapsulated bacteria and, in particular, pneumococcal disease. **Spontaneous bacterial peritonitis** presents with fever, abdominal pain, and peritoneal signs. Although *Pneumococcus* is the most frequent cause of peritonitis, Gram-negative bacteria also are associated with a significant number of cases. Children with nephrotic syndrome and fever or other signs of infection must be evaluated aggressively, with appropriate cultures drawn, and should be treated promptly and empirically with antibiotics. Peritoneal leukocyte counts >250 are highly suggestive of spontaneous bacterial peritonitis.

**Hypercoagulability**

Nephrotic syndrome is a hypercoagulable state resulting from multiple factors: vascular stasis from hemococoncentration and intravascular volume depletion, increased platelet number and aggregability, and changes in coagulation factor levels. There is an increase in hepatic production of fibrinogen along with urinary losses of antithrombotic

*Approximate frequency as a cause of idiopathic nephrotic syndrome. Approximately 10% of cases of adult nephrotic syndrome are a result of various diseases that usually manifest as acute glomerulonephritis.

↑, Elevated; BUN, blood urea nitrogen; C, complement; GBM, glomerular basement membrane; Ig, immunoglobulin; SLE, systemic lupus erythematosus.

Factors such as antithrombin III and protein S. Deep venous thrombosis may occur in any venous bed, including the cerebral venous sinus, renal vein, and pulmonary veins. The clinical risk is low in children (2-5%) compared to adults, but has the potential for serious consequences.

Bibliography is available at Expert Consult.

527.1 Idiopathic Nephrotic Syndrome

Priya Pais and Ellis D. Avner

Approximately 90% of children with nephrotic syndrome have idiopathic nephrotic syndrome. Idiopathic nephrotic syndrome is associated with primary glomerular disease without an identifiable causative disease or drug. Idiopathic nephrotic syndrome includes multiple histologic types: minimal change disease, mesangial proliferation, focal segmental glomerulosclerosis, membranous nephropathy, and membranoproliferative glomerulonephritis.

PATHOLOGY

In minimal change nephrotic syndrome (MCNS) (approximately 85% of total cases of nephrotic syndrome in children), the glomeruli appear normal or show a minimal increase in mesangial cells and matrix. Findings on immunofluorescence microscopy are typically negative, and electron microscopy simply reveals effacement of the epithelial cell foot processes. More than 95% of children with minimal change disease respond to corticosteroid therapy.

*Podocyte expression of SMARCAL1 is presumptive but not yet established. Mutations in another protein, CD2-AP or NEPH1 (a novel protein structurally related to nephrin), cause congenital nephrotic syndrome in mice. A mutational variant in the CD2AP gene has been identified in a few patients with steroid-resistant nephrotic syndrome.

FSGS, focal segmental glomerulosclerosis.

Mesangial proliferation is characterized by a diffuse increase in mesangial cells and matrix on light microscopy. Immunofluorescence microscopy might reveal trace to 1+ mesangial IgM and/or IgA staining. Electron microscopy reveals increased numbers of mesangial cells and matrix as well as effacement of the epithelial cell foot processes. Approximately 50% of patients with this histologic lesion respond to corticosteroid therapy.

In focal segmental glomerulosclerosis (FSGS), glomeruli show lesions that are both focal (present only in a proportion of glomeruli) and segmental (localized to ≥1 intraglomerular tufts). The lesions consist of mesangial cell proliferation and segmental scarring on light microscopy (Fig. 527-2 and see Table 527-2). Immunofluorescence microscopy is positive for IgM and C3 staining in the areas of segmental scarring. Electron microscopy demonstrates segmental scarring of the glomerular tuft with obliteration of the glomerular capillary lumen. Similar lesions may be seen secondary to HIV infection, vesicoureteral reflux, and intravenous use of heroin and other drugs of abuse. Only 20% of patients with FSGS respond to prednisone. The disease is often progressive, ultimately involving all glomeruli, and ultimately leads to end-stage renal disease in most patients.
Bibliography

family history of nephrotic syndrome, and/or the presence of extrarenal findings (e.g., arthritis, rash, anemia), hypertension or pulmonary edema, acute or chronic renal insufficiency, and gross hematuria.

**Diagnosis**

**Recommendations for the Initial Evaluation of Children with Nephrotic Syndrome**

**Confirming the Diagnosis of Nephrotic Syndrome.**

The diagnosis of nephrotic syndrome is confirmed by urinalysis with first morning urine protein:creatinine ratio and serum electrolytes, blood urea nitrogen, creatinine, albumin, and cholesterol levels; evaluation to rule out secondary forms of nephrotic syndrome (children ≥10 yr): complement C3 level, antinuclear antibody, double-stranded DNA and hepatitides B and C, and HIV in high-risk populations; and kidney biopsy (for children ≥12 yr, who are less likely to have MCNS).

The urinalysis reveals 3+ or 4+ proteinuria, and microscopic hematuria is present in 20% of children. A spot urine protein:creatinine ratio should be >2.0. The serum creatinine value is usually normal, but it may be abnormally elevated if there is diminished renal perfusion from contraction of the intravascular volume. The serum albumin level is <2.5 g/dL, and serum cholesterol and triglyceride levels are elevated. Serum complement levels are normal. A renal biopsy is not routinely performed if the patient fits the standard clinical picture of MCNS.

**Treatment**

Children with their first episode of nephrotic syndrome and mild to moderate edema may be managed as outpatients. Such outpatient management is not practiced in all major centers, because the time required for successful education of the family regarding all aspects of the condition can require a short period of hospitalization. The child's parents must be able to recognize the signs and symptoms of the complications of the disease and may be taught how to use a dipstick and interpret the results to monitor for the degree of proteinuria. Tuberculosis must be ruled out prior to starting immunosuppressive therapy with corticosteroids by placing a purified protein derivative or obtaining an interferon release assay, and confirming a negative result.

Children with onset of uncomplicated nephrotic syndrome between 1 and 8 yr of age are likely to have steroid-responsive MCNS, and steroid therapy may be initiated without a diagnostic renal biopsy. Children with features that make MCNS less likely (gross hematuria, hypertension, renal insufficiency, hypocomplementemia, or age <1 yr or >12 yr) should be considered for renal biopsy before treatment.

**Use of Corticosteroids to Treat Minimal Change Nephrotic Syndrome**

Corticosteroids are the mainstay of therapy for MCNS. The treatment guidelines for corticosteroid use presented below are adapted from and based on the 2012 Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines on glomerulonephritis.

**Treatment of Initial Episode of Nephrotic Syndrome**

In children with presumed MCNS, prednisone or prednisolone should be administered as a single daily dose of 60 mg/m²/day or 2 mg/kg/day to a maximum of 60 mg daily for 4-6 wk followed by alternate-day prednisone (starting at 40 mg/m² qod or 1.5 mg/kg qod) for a period ranging from 8 wk to 5 mo, with tapering of the dose. When planning the duration of steroid therapy, the side effects of prolonged corticosteroid administration must be kept in mind.

Approximately 80-90% of children respond to steroid therapy. **Response** is defined as the attainment of remission within the initial 4 wk of corticosteroid therapy. **Remission** consists of a urine protein:creatinine ratio of <0.2 or <1+ protein on urine dipstick for 3 consecutive days. The vast majority of children who respond to prednisone therapy do so within the first 5 wk of treatment.

**Managing the Clinical Sequelae of Nephrotic Syndrome**

**Edema.** Children with severe symptomatic edema, including large pleural effusions, ascites, or severe genital edema, should be hospitalized. In addition to sodium restriction (<1500 mg daily), water/fluid restriction may be necessary if the child is hyponatremic. A swollen scrotum may be elevated with pillows to enhance fluid removal by gravity. Diuresis may be augmented by the administration of loop diuretics (furosemide), orally or intravenously, although extreme caution should be exercised. Aggressive diuresis can lead to intravascular volume depletion and an increased risk for acute renal failure and intravascular thrombosis.

When a patient has severe generalized edema with evidence of intravascular volume depletion (e.g., hypotension, hyperviscosity, tachycardia), IV administration of 25% albumin (0.5-1.0 g albumin/kg) as a slow infusion followed by furosemide (1-2 mg/kg/dose IV) is sometimes necessary. Such therapy should be used only in collaboration with a pediatric nephrologist and mandates close monitoring of volume status, blood pressure, serum electrolyte balance, and renal function. Symptomatic volume overload, with hypertension, heart failure, and pulmonary edema, is a potential complication of parenteral albumin therapy, particularly when administered as rapid infusions.

**Dyslipidemia.** Dyslipidemia should be managed with a low-fat diet. Dietary fat intake should be limited to <30% of calories with saturated fat intake <10% calories. Dietary cholesterol intake should be <300 mg/day. There are insufficient data to recommend the use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors routinely in children with dyslipidemia.

**Infections.** Families of children with nephrotic syndrome should be counseled regarding the signs and symptoms of infections such as cellulitis, peritonitis, and bacteremia. If there is suspicion of infection, a blood culture should be drawn prior to starting empiric antibiotic therapy. In the case of spontaneous bacterial peritonitis, peritoneal fluid should be collected if there is sufficient fluid to perform a paracentesis and sent for cell count, Gram stain, and culture. The antibiotic provided must be of broad enough coverage to include Pneumococcus and Gram-negative bacteria. A 3rd-generation cephalosporin is a common choice of IV antibiotic.

**Thromboembolism.** Children who present with the clinical signs of thromboembolism should be evaluated by appropriate imaging studies to confirm the presence of a clot. Studies to delineate a specific underlying hypercoagulable state are recommended. Anticoagulation therapy in children with thrombotic events appears to be effective—heparin, low-molecular-weight heparin, and warfarin are therapeutic options.

**Obesity and Growth.** Glucocorticoids may increase the body mass index in children who are overweight when steroid therapy is initiated, and these children are more likely to remain overweight. Anticipatory dietary counseling is recommended. Growth may be affected in children who require long-term corticosteroid therapy. Steroid-sparing strategies may improve linear growth in children who require prolonged courses of steroids.

**Relapse of Nephrotic Syndrome.** Relapse of nephrotic syndrome is defined as a urine protein:creatinine ratio of >2 or ≥3+ protein on urine dipstick testing for 3 consecutive days. Relapses are common, especially in younger children, and are often triggered by upper respiratory or gastrointestinal infections. Relapses are usually treated in a manner similar to the initial episode, except that daily prednisone courses are shortened. Daily high-dose prednisone is given until the child has achieved remission, and the regimen is then switched to alternate-day therapy. The duration of alternate day therapy varies depending on the frequency of relapses of the individual child. Children are classified as infrequent relapsers or frequent relapsers, and as being steroid dependent based on the number of relapses in a 12 mo period or their inability to remain in remission following discontinuation of steroid therapy.

**Steroid Resistance.** Steroid resistance is defined as the failure to achieve remission after 8 wk of corticosteroid therapy. Children with steroid-resistant nephrotic syndrome require further evaluation, including a diagnostic kidney biopsy, evaluation of kidney function, and quantitation of urine protein excretion (in addition to urine dipstick testing). Steroid-resistant nephrotic syndrome is
usually caused by FSGS (80%), MCNS, or membranoproliferative glomerulonephritis.

**Implications of Steroid-Resistant Nephrotic Syndrome.** Steroid-resistant nephrotic syndrome, and specifically FSGS, is associated with a 50% risk for end-stage kidney disease within 5 yr of diagnosis if patients do not achieve a partial or complete remission. Persistent nephrotic syndrome is associated with poor patient-reported quality of life, hypertension, serious infections, and thromboembolic events. Children reaching end-stage kidney disease have a greatly reduced life expectancy compared to their peers.

**Alternative Therapies to Corticosteroids in the Treatment of Nephrotic Syndrome.** Steroid-dependent patients, frequent relapers, and steroid-resistant patients are candidates for alternative therapies, particularly if they have severe corticosteroid toxicity (cushingoid appearance, hypertension, cataracts, and/or growth failure). Cyclophosphamide prolongs the duration of remission and reduces the number of relapses in children with frequently relapsing and steroid-dependent nephrotic syndrome. The potential side effects of the drug (neutropenia, disseminated varicella, hemorhagic cystitis, alopecia, sterility, increased risk of future malignancy) should be carefully reviewed with the family before initiating treatment. Cyclophosphamide (2 mg/kg) is given as a single oral dose for a total duration of 8-12 wk. Alternate-day prednisone therapy is often continued during the course of cyclophosphamide administration.

During cyclophosphamide therapy, the white blood cell count must be monitored weekly and the drug should be withheld if the count falls below 5,000/mm³. The cumulative threshold dose above which oligosperma or azoosperma occurs in boys is >250 mg/kg.

Calcineurin inhibitors (cyclosporine or tacrolimus) are recommended as initial therapy for children with steroid-resistant nephrotic syndrome. Children must be monitored for side effects, including hypertension, nephrotoxicity, hirsutism, and gingival hyperplasia. Mycophenolate can maintain remission in children with steroid-dependent or frequently relapsing nephrotic syndrome. Levamisole, an anthelmintic agent with immunomodulating effects that has been shown to reduce the risk of relapse in comparison to prednisone, is not available in the United States. There are also uncontrolled preliminary data regarding prolonged remissions achieved with rituximab, the chimeric monoclonal antibody against CD20, in children with steroid-dependent and/or steroid-resistant nephrotic syndrome. There are no data from randomized clinical trials directly comparing the various corticosteroid-sparing agents. Most children who respond to cyclosporine, tacrolimus, or mycophenolate therapy tend to relapse when the medication is discontinued. Angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers may be helpful as adjunct therapy to reduce proteinuria in steroid-resistant patients.

**Immunizations in Children with Nephrotic Syndrome.** To reduce the risk of serious infections in children with nephrotic syndrome, give full pneumococcal vaccination (with the 13-valent conjugate vaccine and 23-valent polysaccharide vaccine) and influenza vaccination annually to the child and their household contacts; defer vaccination with live vaccines until the prednisone dose is below either 1 mg/kg daily or 2 mg/kg on alternate days. Live virus vaccines are contraindicated in children receiving corticosteroid-sparing agents such as cyclophosphamide or cyclosporine. Following close contact with varicella infection, give immunocompromised children on immunosuppressive agents varicella-zoster immune globulin if available; immunize healthy household contacts with live vaccines to minimize the risk of transfer of infection to the immunosuppressed child, but avoid direct exposure of the child to gastrointestinal or respiratory secretions of vaccinated contacts for 3-6 wk after vaccination.

Table 527-4 provides monitoring recommendations for children with nephrotic syndrome.

effects of the condition and its therapy, children with idiopathic nephrotic syndrome should not be considered chronically ill and should participate in all age-appropriate childhood activities and maintain an unrestricted diet when in remission.

Children with steroid-resistant nephrotic syndrome, most often caused by FSGS, generally have a much poorer prognosis. These children develop progressive renal insufficiency, ultimately leading to end-stage renal disease requiring dialysis or kidney transplantation. Recurrent nephrotic syndrome develops in 30-50% of transplant recipients with FSGS.

Bibliography is available at Expert Consult.

527.2 Secondary Nephrotic Syndrome

Priya Pais and Ellis D. Avner

Nephrotic syndrome can occur as a secondary feature of many forms of glomerular disease. Membranous nephropathy, membranoproliferative glomerulonephritis, postinfectious glomerulonephritis, lupus nephritis, and Henoch-Schönlein purpura nephritis can all have a nephrotic component (see Tables 527-1 and 527-2). Secondary nephrotic syndrome should be suspected in patients >8 yr and those with hypertension, renal dysfunction, extrarenal symptoms (rash, arthralgias, fever), or depressed serum complement levels. In certain areas of the world, malaria and schistosomiasis are the leading causes of nephrotic syndrome. Other infectious agents associated with nephrotic syndrome include hepatitis B virus, hepatitis C virus, filaria, leprosy, and HIV.

Nephrotic syndrome has been associated with malignancy, particularly in the adult population. In patients with solid tumors, such as carcinomas of the lung and gastrointestinal tract, the renal pathology often resembles membranous glomerulopathy. Immune complexes composed of tumor antigens and tumor-specific antibodies presumably mediate the renal involvement. In patients with lymphomas, particularly Hodgkin lymphoma, the renal pathology most often resembles MCNS. The proposed mechanism of the nephrotic syndrome is that the lymphoma produces a lymphokine that increases permeability of the glomerular capillary wall. Nephrotic syndrome can develop before or after the malignancy is detected, resolve as the tumor regresses, and return if the tumor recurs.

Nephrotic syndrome has also developed during therapy with numerous drugs and chemicals. The histologic picture can resemble membranous glomerulopathy (penicillamine, captopril, gold, nonsteroidal antiinflammatory drugs, mercury compounds), MCNS (probenecid, ethamsuximide, methimazole, lithium), or proliferative glomerulonephritis (procainamide, chlorpropamide, phenytoin, trimethadione, paramethadione).

Bibliography is available at Expert Consult.

527.3 Congenital Nephrotic Syndrome

Priya Pais and Ellis D. Avner

Nephrotic syndrome (massive proteinuria, hypoalbuminemia, edema, and hypercholesterolemia) has a poorer prognosis when it occurs in the 1st yr of life, when compared to nephrotic syndrome manifesting in childhood. Congenital nephrotic syndrome is defined as nephrotic syndrome manifesting at birth or within the 1st 3 mo of life. Congenital nephrotic syndrome may be classified as primary or as secondary to a number of etiologies such as in utero infections (cytomegalovirus, toxoplasmosis, syphilis, hepatitides B and C, HIV), infantile systemic lupus erythematosus, or mercury exposure.

Primary congenital nephrotic syndrome is due to a variety of syndromes inherited as autosomal recessive disorders (see Table 527-3). A number of structural and functional abnormalities of the glomerular filtration barrier causing congenital nephrotic syndrome have been elucidated. In a large European cohort of children with congenital nephrotic syndrome, 85% carried disease-causing mutations in 4 genes (NPHS1, NPHS2, WT1, and LAMB2), the first 3 of which encode components of the glomerular filtration barrier. The Finnish type of congenital nephrotic syndrome is caused by mutations in the NPHS1 or NPHS2 gene, which encodes nephrin and podocin, critical components of the slit diaphragm. Affected infants most commonly present at birth with edema caused by massive proteinuria, and they are typically delivered with an enlarged placenta (>25% of the infant's weight). Severe hypoalbuminemia, hyperlipidemia, and hypogammaglobulinemia result from loss of filtering selectivity at the glomerular filtration barrier. Prenatal diagnosis can be made by the presence of elevated maternal and amniotic ß-fetoprotein levels.

Denys-Drash syndrome is caused by mutations in the WT1 gene, which results in abnormal podocyte function. Patients present with early-onset nephrotic syndrome, progressive renal insufficiency, ambiguous genitalia, and Wilms tumors.

Mutations in the LAMB2 gene, seen in Pierson syndrome, lead to abnormalities of ß-laminin, a critical component of glomerular and ocular basement membranes. In addition to congenital nephrotic syndrome, affected infants display bilateral microcoria (fixed narrowing of the pupil).

Regardless of the etiology of congenital nephrotic syndrome, diagnosis is made clinically in newborns or infants who demonstrate severe generalized edema, poor growth and nutrition with hypoalbuminemia, increased susceptibility to infections, hypothyroidism (from urinary loss of thyroxin-binding globulin), and increased risk of thrombotic events. Most infants have progressive renal insufficiency.

Secondary congenital nephrotic syndrome can resolve with treatment of the underlying cause, such as syphilis (Table 527-5). The management of primary congenital nephrotic syndrome includes intensive supportive care with intravenous albumin and diuretics, regular administration of intravenous γ-globulin, and aggressive nutritional support (often parenteral), while attempting to pharmacologically decrease urinary protein loss with angiotensin-converting enzyme.
inhibitors, angiotensin II receptor inhibitors, and prostaglandin synthesis inhibitors, or even unilateral nephrectomy. If conservative management fails and patients suffer from persistent anasarca or repeated severe infections, bilateral nephrectomies are performed and chronic dialysis is initiated. Renal transplantation is the definitive treatment of congenital nephrotic syndrome, though recurrence of the nephrotic syndrome has been reported to occur after transplantation.

Bibliography

Tubular Disorders

Chapter 528

Tubular Function

Rajasree Sreedharan and Ellis D. Avner

Water and electrolytes are freely filtered at the level of the glomerulus. Thus, the electrolyte content of ultrafiltrate at the beginning of the proximal tubule is similar to that of plasma. Carefully regulated processes of tubular reabsorption and/or tubular secretion determine the final water content and electrolyte composition of urine. Bulk movement of solute tends to occur in the proximal portions of the nephron, and fine adjustments tend to occur distally (see Chapter 55).

SODIUM

Sodium is essential in maintaining extracellular fluid balance and, thus, volume status. The kidney is capable of effecting large changes in sodium excretion in a variety of normal and pathologic states.

There are 4 main sites of sodium transport. Approximately 60% of sodium is absorbed in the proximal tubule by coupled transport with glucose or amino acids, 25% in the ascending loop of Henle (mediated by NKCC2, the bumetanide-sensitive sodium-potassium 2 chloride transporter), and 15% in the distal tubule (mediated by NCCT, the thiazide-sensitive sodium chloride cotransporter) and collecting tubule (mediated by ENaC, the epithelial sodium channel).

The urinary excretion of sodium normally approximates the sodium intake of 2-6 mEq/kg/24 hr for a child consuming a typical American diet, minus 1-2 mEq/kg/24 hr required for normal metabolic processes. However, in states of volume depletion (dehydration, blood loss) or decreased effective circulating blood volume (septic shock, hypoaalbuminemic states, heart failure), there may be a dramatic decrease in urinary sodium excretion to as low as 1 mEq/L. Changes in systemic volume status are detected by (1) baroreceptors in the atra, afferent arteriole, and carotid sinus and (2) by the macula densa, which detects changes in chloride delivery.

The major hormonal mechanisms mediating sodium balance include the renin–angiotensin–aldosterone axis, atrial natriuretic factor, and norepinephrine. Angiotensin II and aldosterone increase sodium reabsorption in the proximal tubule and distal tubule, respectively. Norepinephrine, released in response to volume depletion, does not directly act on tubular transport mechanisms but affects sodium balance by decreasing renal blood flow, thus decreasing the filtered load of sodium as well as stimulating renin release. With more severe volume depletion, antidiuretic hormone is also released (see Chapter 530). Sodium excretion is promoted by atrial natriuretic factor and suppression of renin.

POTASSIUM

Extracellular potassium homeostasis is regulated because small changes in plasma potassium concentrations have dramatic effects on cardiac, neural, and neuromuscular function (see Chapter 55.4). Essentially, all filtered potassium is fully reabsorbed in the proximal tubule. Therefore, urinary excretion of potassium is completely dependent on tubular secretion by potassium channels present in the principal cells of the collecting tubule. Factors that promote potassium secretion include aldosterone, increased sodium delivery to the distal nephron, and increased urine flow rate.

CALCIUM

A significant portion of filtered calcium (70%) is reabsorbed in the proximal tubule. Additional calcium is reabsorbed in the ascending loop of Henle (20%) and the distal tubule and collecting duct (5-10%). Calcium is reabsorbed by passive movement between cells (paracellular absorption) in a process driven by sodium chloride reabsorption and potassium recycling into the lumen. In addition, calcium uptake is actively regulated by calcium receptors, specific transporters, and calcium channels. Factors that promote calcium reabsorption include parathyroid hormone (released in response to hypocalcemia), calcitriol, vitamin D, thiazide diuretics, and volume depletion (see Chapter 570). Factors that promote calcium excretion include volume expansion, increased sodium intake, and diuretics such as mannitol and furosemide.

PHOSPHATE

The majority of filtered phosphate is reabsorbed in the proximal tubule by active transport. Reabsorption is increased by dietary phosphorus restriction, volume contraction, and growth hormone. Parathyroid hormone and volume expansion increase phosphate excretion.

MAGNESIUM

Approximately 25% of filtered magnesium is reabsorbed in the proximal tubule. Modulation of renal magnesium excretion occurs primarily in the ascending loop of Henle, with some contribution of the distal convoluted tubule. Although specific magnesium transporters have been identified, the precise mechanisms by which they are regulated remain unclear.

ACIDIFICATION AND CONCENTRATING MECHANISMS

Acidification and concentration are addressed in the sections on renal tubular acidosis and nephrogenic diabetes insipidus, respectively (see Chapters 529 and 530).

DEVELOPMENTAL CONSIDERATIONS

Tubular transport capabilities of neonates (especially premature infants) and young infants are less than those of adults. Although nephrogenesis (the formation of new glomerular/tubular units) is complete by about 36 wk of gestation, significant tubular maturation occurs during infancy. Renal tubular immaturity, reduced glomerular filtration rate, decreased concentrating gradient, and diminished responsiveness to antidiuretic hormone are characteristic of young infants. These factors can contribute to impaired regulation of water, solute, and electrolyte and acid–base homeostasis, particularly during times of acute illness.

Bibliography is available at Expert Consult.
Bibliography
Renal tubular acidosis (RTA) is a disease state characterized by a normal anion gap (hyperchloremic) metabolic acidosis in the setting of normal or near-normal glomerular filtration rate. There are 4 main types: proximal (type II) RTA, classic distal (type I) RTA, hyperkalemic (type IV) RTA, and combined proximal and distal (type III). Proximal RTA results from impaired bicarbonate reabsorption and distal RTA from failure to secrete acid. Either of these defects may be inherited and persistent from birth or acquired, as is seen more commonly in clinical practice.

NORMAL URINARY ACIDIFICATION

Kidneys contribute to acid–base balance by reabsorption of filtered bicarbonate (HCO$_3^-$) and excretion of hydrogen ion (H$^+$) produced every day. Hydrogen ion secretion from tubule cells into the lumen is key in the reabsorption of HCO$_3^-$, and the formation of titratable acid (H$^+$ bound to buffers such as HPO$_4^{2-}$), and ammonium ions (NH$_4^+$). Because loss of filtered HCO$_3^-$ is equivalent to addition of H$^+$ to the body, all filtered bicarbonate should be absorbed before dietary H$^+$ can be excreted. Approximately 90% of filtered bicarbonate is absorbed in the proximal tubule, and the remaining 10% in the distal segments, mostly the thick ascending limb and outer medullary collecting tubule (Fig. 529-1). In the proximal tubule and thick ascending limb of the loop of Henle, H$^+$ from water is secreted by the Na$^+$-H$^+$ exchanger on the luminal membrane. H$^+$ combines with filtered bicarbonate resulting in the formation of H$_2$CO$_3$, which splits into water and CO$_2$ in the presence of carbonic anhydrase IV. CO$_2$ diffuses freely back into the cell, combines with OH$^-$ (from H$_2$O) to form HCO$_3^-$ in the presence of carbonic anhydrase II, and returns to the systemic circulation via a Na$^+$-HCO$_3^-$ cotransporter situated at the basolateral membrane of the cell. In the collecting tubule, H$^+$ is secreted into lumen by H$^+$-ATPase (adenosine triphosphatase) and HCO$_3^-$ is returned to the systemic circulation by the HCO$_3^-$-Cl$^-$ exchanger located on the basolateral membrane. The H$^+$ secreted proximally and distally in excess of the filtered HCO$_3^-$ is excreted in the urine either as titratable acid or as NH$_4^+$.

529.1 Proximal (Type II) Renal Tubular Acidosis

Rajasree Sreedharan and Ellis D. Avner

PATHOGENESIS

Proximal RTA can be inherited and persistent from birth or occur as a transient phenomenon during infancy. Although rare, it may be primary and isolated. Proximal RTA usually occurs as a component of global proximal tubular dysfunction or Fanconi syndrome, which is characterized by low-molecular-weight proteinuria, glycosuria, phosphaturia, aminoaciduria, and proximal RTA. Table 529-1 outlines the causes of proximal RTA (pRTA) and Fanconi syndrome. Many of these causes are inherited disorders. In addition to cystinosis and Lowe syndrome, autosomal recessive and dominant pRTA are addressed further in this section. Other inherited forms of Fanconi syndrome include galactosemia (see Chapter 87.2), hereditary fructose intolerance (see Chapter 87.3), tyrosinemia (see Chapter 85.2), and Wilson disease (see Chapter 357.2). Dent disease or X-linked nephrolithiasis, is discussed in Chapter 531.3. In children, an important form of secondary Fanconi syndrome is exposure to ifosfamide, a component of many treatment regimens for Wilms tumor and other solid tumors.

Autosomal Recessive Disease

Isolated autosomal recessive pRTA is caused by mutations in the gene encoding the sodium bicarbonate cotransporter NBC1. It manifests with ocular abnormalities (band keratopathy, cataracts, and glaucoma, often leading to blindness), short stature, enamel defects of the teeth, intellectual impairment, and occasionally basal ganglia calcification along with pRTA. Autosomal dominant pattern of inheritance has been identified in a single pedigree with 9 members presenting with hyperchloremic metabolic acidosis, normal ability to acidify urine, normal renal function, and growth retardation.

Cystinosis

Cystinosis is a systemic disease caused by a defect in the metabolism of cysteine that results in accumulation of cystine crystals in most of the major organs of the body, notably the kidney, liver, eye, and brain. It occurs at an incidence of 1:100,000 to 1:200,000. In certain populations, such as French Canadians, the incidence is much higher. At least 3 clinical patterns have been described. Young children with the most severe form of the disease (infantile or nephropathic cystinosis) present in the 1st 2 yr of life with severe tubular dysfunction and growth failure. If the disease is not treated, the children develop end-stage renal disease by the end of their 1st decade. A milder form of the disease manifests in adolescents and is characterized by less-severe tubular abnormalities and a slower progression to renal failure. A benign adult form with no renal involvement also exists.

Cystinosis is caused by mutations in the CTNS gene, which encodes a novel protein, cystinosin. Cystinosin is thought to be an H$^+$-driven lysosomal cystine transporter. Genotype–phenotype studies demonstrate that patients with severe nephropathic cystinosis carry mutations that lead to complete loss of cystinosin function. Patients with milder clinical disease have mutations that lead to expression of partially functional protein. Patients with nephropathic cystinosis present with clinical manifestations reflecting their pronounced tubular dysfunction and Fanconi syndrome, including polyuria and polydipsia, growth failure, and rickets. Fever, caused by dehydration or diminished sweat production, is common. Patients are typically fair skinned and blond because of diminished pigmentation. Ocular presentations include photophobia, retinopathy, and impaired visual acuity. Patients also can develop hypothyroidism, hepatosplenomegaly, and delayed sexual

maturation. With progressive tubulointerstitial fibrosis, renal insufficiency is invariant.

The diagnosis of cystinosis is suggested by the detection of cystine crystals in the cornea and confirmed by measurement of increased leukocyte cystine content. Prenatal testing is available for at-risk families.

Treatment of cystinosis is directed at correcting the metabolic abnormalities associated with Fanconi syndrome or chronic renal failure. In addition, specific therapy is available with cysteamine, which binds to cystine and converts it to cysteine. This facilitates lysosomal transport and decreases tissue cystine. Oral cysteamine does not achieve adequate levels in ocular tissues, so additional therapy with cysteamine eyedrops is required. Early initiation of the drug can prevent or delay deterioration of renal function. Patients with growth failure that does not improve with cysteamine might benefit from treatment with growth hormone. Kidney transplantation is a viable option in patients with renal failure. With prolonged survival, additional complications may become evident, including central nervous system abnormalities, muscle weakness, swallowing dysfunction, and pancreatic insufficiency. It is unclear whether long-term cysteamine therapy will decrease these complications.

Lowe Syndrome

Lowe syndrome (oculocerebrorenal syndrome of Lowe) is a rare X-linked disorder characterized by congenital cataracts, mental retardation, and Fanconi syndrome. The disease is caused by mutations in the OCRL1 gene, which encodes the phosphatidylinositol polyphosphate 5-phosphatase protein. The abnormalities seen in Lowe syndrome are thought to be caused by abnormal transport of vesicles within the Golgi apparatus. Kidneys show nonspecific tubulointerstitial changes. Thickening of glomerular basement membrane and changes in proximal tubule mitochondria are also seen.
Patients with Lowe syndrome typically present in infancy with cataracts, progressive growth failure, hypotonia, and Fanconi syndrome. Significant proteinuria is common. Blindness and renal insufficiency often develop. Characteristic behavioral abnormalities are also seen, including tantrums, stubbornness, stereotypy (repetitive behaviors), and obsessions. There is no specific therapy for the renal disease or neurologic deficits. Cataract removal is generally required.

**CLINICAL MANIFESTATIONS OF PROXIMAL RENAL TUBULAR ACIDOSIS AND FANCONI SYNDROME**

Patients with isolated, sporadic, or inherited pRTA present with growth failure in the 1st yr of life. Additional symptoms can include polyuria, dehydration (from sodium loss), anorexia, vomiting, constipation, and hypotonia. Patients with primary Fanconi syndrome have additional symptoms, secondary to phosphate wasting, such as rickets. Those with systemic diseases present with additional signs and symptoms specific to their underlying disease. A non-anion gap metabolic acidosis is present. Urinalysis in patients with isolated pRTA is generally unremarkable. The urine pH is acidic (<5.5) because distal acidification mechanisms are intact in these patients. Urinary indices in patients with Fanconi syndrome demonstrate varying degrees of phosphaturia, aminoaciduria, glycosuria, uricosuria, and elevated urinary sodium or potassium. Depending on the nature of the underlying disorder, laboratory evidence of chronic renal insufficiency, including elevated serum creatinine, may be present.

### 529.2 Distal (Type I) Renal Tubular Acidosis

**PATHOGENESIS**

Distal RTA can be sporadic or inherited. It can also occur as a complication of inherited or acquired diseases of the distal tubules. Primary or secondary causes of distal RTA can result in damaged or impaired functioning of one or more transporters or proteins involved in the acidification process, including the H\(^+\)/ATPase, the HCO\(_3\)\(^-\)−/Cl\(^-\) anion exchangers, or the components of the aldosterone pathway. Because of impaired hydrogen ion excretion, urine pH cannot be reduced to <5.5, despite the presence of severe metabolic acidosis. Loss of sodium bicarbonate distally, owing to lack of H\(^+\) to bind to in the tubular lumen (see Fig. 529–1), results in increased chloride absorption and hyperchloremia. Inability to secrete H\(^+\) is compensated by increased K\(^+\) secretion distally, leading to hypokalemia. **Hypercalcuria** is usually present and can lead to nephrocalcinosis or nephrolithiasis. Chronic metabolic acidosis also impairs urinary citrate excretion. **Hypocitraturia** further increases the risk of calcium deposition in the tubules. Bone disease is common, resulting from mobilization of organic components from bone to serve as buffers to chronic acidosis.

**CLINICAL MANIFESTATIONS**

Distal RTA shares features with those of pRTA, including non-anion gap metabolic acidosis and growth failure; distinguishing features of distal RTA include nephrocalcinosis and hypercalciumia. The phosphate and massive bicarbonate wasting characteristic of pRTA is generally absent. Table 529–1 lists the causes of primary and secondary distal RTA. Although inherited forms are rare, 3 specific inherited forms of distal RTA have been identified, including an autosomal recessive form associated with sensorineural deafness.

**Medullary sponge kidney** is a relatively rare sporadic disorder in children, although not uncommon in adults. It is characterized by cystic dilation of the terminal portions of the collecting ducts as they enter the renal pyramids. Ultrasonographically, patients often have medullary nephrocalcinosis. Although patients with this condition typically maintain normal renal function through adulthood, complications include nephrolithiasis, pyelonephritis, hyposthenuria (inability to concentrate urine), and distal RTA. Associations of medullary sponge kidney with Beckwith-Wiedemann syndrome or hemihypertrophy have been reported.

### 529.3 Hyperkalemic (Type IV) Renal Tubular Acidosis

**PATHOGENESIS**

Type IV RTA occurs as the result of impaired aldosterone production (**hypoaldosteronism**) or impaired renal responsiveness to aldosterone (**pseudohypoaldosteronism**). Acidosis results because aldosterone has a direct effect on the H\(^+\)/ATPase responsible for hydrogen secretion. In addition, aldosterone is a potent stimulant for potassium secretion in the collecting tubule; consequently, lack of aldosterone results in hyperkalemia. This further affects acid–base status by inhibiting ammoniagenesis and, thus, H\(^+\) excretion. Aldosterone deficiency typically occurs as a result of adrenal gland disorders such as Addison disease or some forms of congenital adrenal hyperplasia. In children, aldosterone unresponsiveness is a more common cause of type IV RTA. This can occur transiently, during an episode of acute pyelonephritis or acute urinary obstruction, or chronically, particularly in infants and children with a history of obstructive uropathy. The latter patients can have significant hyperkalemia, even in instances when renal function is normal or only mildly impaired. Rare examples of inherited forms of type IV RTA have been identified.

**CLINICAL MANIFESTATIONS**

Patients with type IV RTA can present with growth failure in the first few years of life. Polyuria and dehydration (from salt wasting) are common. Rarely, patients (especially those with pseudohypoaldosteronism type 1) present with life-threatening hyperkalemia. Patients with obstructive uropathies can present acutely with signs and symptoms of pyelonephritis, such as fever, vomiting, and foul-smelling urine. Laboratory tests reveal a hyperkalemic non–anion gap metabolic acidosis. Urine may be alkaline or acidic. Elevated urinary sodium levels with inappropriately low urinary potassium levels reflect the absence of aldosterone effect.

**DIAGNOSTIC APPROACH TO RENAL TUBULAR ACIDOSIS**

The first step in the evaluation of a patient with suspected RTA is to confirm the presence of a normal anion gap metabolic acidosis, identify electrolyte abnormalities, assess renal function, and rule out other causes of bicarbonate loss such as diarrhea (see Chapter 55). The finding of normal or low potassium suggests type I or II. The blood anion gap should be calculated using the formula \[\text{[Na}^+\text{] – [Cl}^–\text{] – [HCO}_3\text{]}.\] Values of <12 demonstrate the absence of an anion gap. Values of >20 indicate the presence of an anion gap. If such an anion gap is found, then other diagnoses (lactic acidosis, inborn errors of
metabolism, ingested toxins) should be investigated. If tachypnea is noted, evaluation of an arterial blood gas might help to rule out the possibility of a mixed acid-base disorder primarily involving respiratory and metabolic components. A detailed history, with particular attention to growth and development, recent or recurrent diarrheal illnesses, and a family history of mental retardation, failure to thrive, end-stage renal disease, infant deaths, or miscarriages is essential. Physical examination should determine growth parameters and volume status as well as the presence of any dysmorphic features suggesting an underlying syndrome.

Once the presence of a non–anion gap metabolic acidosis is confirmed, urine pH can help distinguish distal from proximal causes. A urine pH <5.5 in the presence of acidosis suggests pRTA, whereas patients with distal RTA typically have a urine pH >6.0. The urine anion gap (\([\text{urine Na}^+ + \text{urine K}^+] - \text{urine Cl}^-\)) is sometimes calculated to confirm the diagnosis of distal RTA. A positive gap suggests a deficiency of ammoniagenesis and, thus, the possibility of a distal RTA. A negative gap is consistent with proximal tubule bicarbonate wasting (gastrointestinal bicarbonate wasting). A urinalysis should also be obtained to determine the presence of glycosuria, proteinuria, or hematuria, suggesting more global tubular damage or dysfunction. Random or 24 hr urine calcium and creatinine measurements will identify hypercalciuria. Renal ultrasonography should be performed to identify underlying structural abnormalities such as obstructive uropathies as well as to determine the presence of nephrocalcinosis (Fig. 529-2).

**TREATMENT AND PROGNOSIS**

The mainstay of therapy in all forms of RTA is bicarbonate replacement. Patients with pRTA often require large quantities of bicarbonate, up to 20 mEq/kg/24 hr, in the form of sodium bicarbonate or sodium citrate solution (Bicitra or Shoel solution). The base requirement for distal RTAs is generally in the range of 2-4 mEq/kg/24 hr, although patients’ requirements can vary. Patients with Fanconi syndrome usually require phosphate supplementation. Patients with distal RTA should be monitored for the development of hypercalciuria. Those with symptomatic hypercalciuria (recurrent episodes of gross hematuria), nephrocalcinosis, or nephrolithiasis can require thiazide diuretics to decrease urine calcium excretion. Patients with type IV RTA can require chronic treatment for hyperkalemia with sodium-potassium exchange resin (Kayexalate).

Prognosis of RTA depends to a large part on the nature of any existing underlying disease. Patients with treated isolated proximal or distal RTA generally demonstrate improvement in growth, provided serum bicarbonate levels can be maintained in the normal range. Patients with systemic illness and Fanconi syndrome can have ongoing morbidity with growth failure, rickets, and signs and symptoms related to their underlying disease.

Bibliography is available at Expert Consult.

### 529.4 Rickets Associated with Renal Tubular Acidosis

**Russell W. Chesney**

Rickets may be present in primary RTA, particularly in type II or pRTA. Hypophosphatemia and phosphaturia are common in the renal tubular acids, which are also characterized by hyperchloremic metabolic acidosis, various degrees of bicarbonaturia, and, often, hypercalciuria and hyperkaluria. Bone demineralization without overt rickets usually is detected in type I and distal RTA. This metabolic bone disease may be characterized by bone pain, growth retardation, osteopenia, and, occasionally, pathologic fractures. Although acute metabolic acidosis in vitamin D–deficient animals can impair the conversion of 25-hydroxyvitamin D (25[OH]D) to 1,25-dihydroxyvitamin D (1,25[OH]2D), resulting in reduced levels of this active metabolite, the circulating levels of 1,25(OH)2D in patients with either type of RTA are generally normal. If patients with RTA have chronic renal insufficiency, serum 1,25(OH)2D levels are reduced in relation to the degree of renal impairment.

Bone demineralization in distal RTA probably relates to dissolution of bone because the calcium carbonate in bone serves as a buffer against the metabolic acidosis due to the hydrogen ions retained by patients with RTA.

Administration of sufficient bicarbonate to reverse acidosis reverses bone dissolution and the hypercalciuria that is common in distal RTA. Proximal RTA is treated with both bicarbonate and oral phosphate supplements to heal rickets. Doses of phosphate similar to those used in familial hypophosphatemia or Fanconi syndrome may be indicated. Vitamin D is required to offset the secondary hyperparathyroidism that complicates oral phosphate therapy. Following therapy, growth in patients with type II (proximal) RTA is greater than in patients with primary Fanconi syndrome. In addition, “double osteomalacia” may be evident when patients with either type of RTA also have vitamin D deficiency.
**Bibliography**

Nephrogenic diabetes insipidus (NDI) is a rare congenital or, more commonly, acquired, disorder of water metabolism characterized by an inability to concentrate urine, even in the presence of antidiuretic hormone (ADH). The most common pattern of inheritance in congenital NDI is as an X-linked recessive disorder. Rarely, affected females are seen, presumably secondary to partial X-chromosome inactivation. Approximately 10% of cases of congenital NDI are inherited as autosomal dominant or recessive disorders, with males and females affected equally. The clinical phenotype of autosomal recessive forms is similar to that of the X-linked form. Secondary (acquired), either partial or complete, forms of NDI are not uncommon. They may be seen in many disorders affecting renal tubular...
function including obstructive uropathies, acute or chronic renal failure, renal cystic diseases, interstitial nephritis, nephrocalcinosis, or toxic nephropathy caused by hypokalemia, hypercalcemia, lithium, or amphotericin B.

**PATHOGENESIS**

The ability to concentrate urine (and thus absorb water) requires the delivery of urine to the collecting tubule; an intact concentrating gradient in the renal medulla; and the ability to modulate water permeability in the collecting tubule by ADH. ADH (also called arginine vasopressin [AVP]), is synthesized in the hypothalamus and stored in the posterior pituitary. Under basal situations, the collecting tubule is impermeable to water. However, in response to increased serum osmolality (as detected by osmoreceptors in the hypothalamus) and/or severe volume depletion, ADH is released into the systemic circulation. It then binds to its receptor, vasopressin V₂ (AVPR₂), on the basolateral membrane of the collecting tubule cell. Binding of the hormone to its receptor activates a cyclic adenosine monophosphate–dependent cascade that results in movement of preformed water channels (aquaporin 2 [AQP2]) to the luminal membrane of the collecting duct, rendering it permeable to water.

Defects in the AVPR₂ gene cause the more common X-linked form of NDI. Mutations in the AQP2 gene have been identified in patients with the rarer autosomal dominant and recessive forms. Prenatal testing is available for families at risk for X-linked NDI. Patients with secondary forms of NDI can have ADH resistance owing to defective aquaporin expression (lithium intoxication). Secondary ADH resistance usually occurs as the result of loss of the hypertonic medullary gradient as a result of solute diuresis or tubular damage, resulting in the inability to absorb sodium or urea.

**CLINICAL MANIFESTATIONS**

Patients with congenital NDI typically present in the newborn period with massive polyuria, volume depletion, hypernatremia, and hyperthermia. Irritability and crying are common features. Constipation and poor weight gain are also seen. After multiple episodes of hypernatremic dehydration, patients can have developmental delay and mental retardation. Enuresis, caused by large urine volumes, is common. Because of the need to consume large volumes of water during the day, patients often have diminished appetite and poor food intake. However, even with adequate caloric supplementation, patients still exhibit growth abnormalities. Patients with congenital NDI also exhibit behavioral problems, including hyperactivity and short-term memory problems. Patients with the secondary form generally present later in life, primarily with hypernatremia and polyuria. Associated symptoms such as developmental delay and behavioral abnormalities are less common in this latter group.

**DIAGNOSIS**

The diagnosis is suggested in a male infant with polyuria, hypernatremia, and diluted urine. Simultaneous serum and urine osmolality measurements should be obtained. If the serum osmolality value is 290 mOsm/kg or higher with a simultaneous urine osmolality value of <290 mOsm/kg, a formal water deprivation test is not necessary. Because the differential diagnosis includes causes of central diabetes insipidus, the inability to respond to ADH (and thus the presence of NDI) should then be confirmed by the administration of vasopressin (10-20 µg intranasally) followed by serial urine and serum osmolality measurements hourly for 4 hr. In patients with possible “partial” or secondary diabetes insipidus, in whom the initial serum osmolality value may be <290 mOsm/kg, a water-deprivation test should be considered. Fluids should be withheld and urine and serum osmolalities measured periodically until the serum osmolality value is >290 mOsm/kg; vasopressin is then given as before. Criteria for premature termination of a water-deprivation test include a decrease in body weight of >3%. If NDI is confirmed or suspected, additional evaluation should include a detailed history to assess possible toxic exposures, determination of renal function by serum creatinine and blood urea nitrogen levels, and renal ultrasonography to identify obstructive uropathies or cystic disease. Because of massive urine output, patients with congenital NDI can have nonobstructive hydronephrosis of varying severity.

**TREATMENT AND PROGNOSIS**

Treatment of NDI includes maintenance of adequate fluid intake and access to free water, minimizing urine output by limiting solute load with a low-osmolal, low-sodium diet, and administering medications directed at decreasing urine output. For infants, human milk or a low-solute formula, such as Similac PM 60/40, is preferred. Most infants with congenital NDI require gastrostomy or nasogastric feedings to ensure adequate fluid administration throughout the day and night. Sodium intake in older patients should be <0.7 mEq/kg/24 hr. Thiazide diuretics (2-3 mg/kg/24 hr of hydrochlorothiazide) effectively induce sodium loss and stimulate proximal tubule reabsorption of water. Potassium-sparing diuretics, in particular, amiloride (0.3 mg/kg/24 hr in 3 divided doses), are often indicated. Patients who have an inadequate response to diuretics alone might benefit from the addition of indomethacin (2 mg/kg/24 hr), which has an additive effect in reducing water excretion in some patients. Renal function must be monitored closely in such patients because indomethacin can cause deterioration in renal function over time. Patients with secondary NDI might not require medications but should have access to free water. Such patients should have serum electrolytes and volume status monitored closely, particularly during periods of superimposed acute illnesses.

Prevention of recurrent dehydration and hypernatremia in patients with congenital NDI has significantly improved the neurodevelopmental outcome of these patients. However, behavioral issues remain a significant problem. In addition, chronic use of nonsteroidal antiinflammatory drugs can predispose patients to renal insufficiency. Prognosis of patients with secondary NDI generally depends on the nature of the underlying disease.

Chapter 531

Bartter and Gitelman Syndromes and Other Inherited Tubular Transport Abnormalities

531.1 Bartter Syndrome

Rajasree Sreedharan and Ellis D. Avner

Bartter syndrome is a group of disorders characterized by hypokalemic metabolic alkalosis with hypercalciuria and salt wasting (see Chapter 55) (Table 531-1). Antenatal Bartter syndrome (types I, II, and IV; also called hyperprostaglandin E syndrome) typically manifests in infancy and has a more-severe phenotype than classic Bartter syndrome (type III); perinatal onset includes maternal polyhydramnios, neonatal salt wasting, and severe episodes of recurrent dehydration. The milder
phenotype, **classic** Bartter syndrome, manifests in childhood with failure to thrive and a history of recurrent episodes of dehydration. A phenotypically related disease, Gitelman syndrome, has a distinct genetic defect and is discussed in Chapter 531.2 (Table 531-1). One distinct variant of antenatal Bartter syndrome is associated with sensorineural deafness (type IV).

**PATHOGENESIS**

The biochemical features of Bartter syndrome, including hypokalemic metabolic alkalosis with hypercalciuria, resemble those seen with chronic use of loop diuretics and reflect a defect in sodium, chloride, and potassium transport in the ascending loop of Henle. The loss of sodium and chloride, with resultant volume contraction, stimulates the renin–angiotensin II–aldosterone axis. Aldosterone promotes sodium uptake and potassium secretion, exacerbating the hypokalemia. It also stimulates hydrogen ion secretion distally, worsening the metabolic alkalosis. Hypokalemia stimulates prostaglandin synthesis, which further activates the renin–angiotensin II–aldosterone axis. Bartter syndrome has been associated with 5 distinct genetic defects in loop of Henle transporters (see Table 531-1). Each contributes, in some manner, to sodium and chloride transport. Mutations in the genes that encode the Na+/K+/2Cl⁻ transporter (NKCC2, the site of action of furosemide), the luminal potassium channel (ROMK), combined chloride channel (CLC-Ka, CLC-Kb), or subunit of chloride channels (barttin) cause neonatal Bartter syndrome. Isolated defects in the genes that produce a specific basolateral chloride channel (CLC-Kb) cause classic Bartter syndrome.

**CLINICAL MANIFESTATIONS**

A history of maternal polyhydramnios with or without prematurity may be elicited. Dysmorphic features, including triangular faces, protruding ears, large eyes with strabismus, and drooping mouth may be present on physical examination. Consanguinity suggests the presence of an autosomal recessive disorder. Older children can have a history of recurrent episodes of polyuria with dehydration, failure to thrive, nonspecific fatigue, dizziness and chronic constipation. Older children may also present with muscle cramps and weakness secondary to chronic hypokalemia. Blood pressure is usually normal, although patients with the antenatal form can have severe salt wasting, resulting in dehydration and hypotension. Serum chemistry reveals the classic biochemical abnormalities of a hypokalemic metabolic alkalosis. Renal function is typically normal. Urinary calcium levels are typically elevated, as are urinary potassium and sodium levels. Serum renin, aldosterone, and prostaglandin E levels are often markedly elevated, particularly in the more-severe antenatal form. Nephrocalcinosis, resulting from hypercalciuria, may be seen on ultrasound examination (types I and II).

**DIAGNOSIS**

The diagnosis is usually made based on clinical presentation and laboratory findings. The diagnosis in the neonate or infant is suggested by severe hypokalemia, usually <2.5 mmol/L, with metabolic alkalosis. Hypercalciuria is typical; hypomagnesemia is seen in a minority of patients but is more common in Gitelman syndrome. Because features of Bartter syndrome resemble chronic use of loop diuretics, diuretic abuse should be considered in the differential diagnosis, even in young children. Chronic vomiting can also give a similar clinical picture but can be distinguished by measurement of urinary chloride, which is elevated in Bartter syndrome and low in patients with chronic vomiting. Kidneys demonstrate hyperplasia of the juxtaplomerular apparatus. Renal biopsy is rarely performed to diagnose this condition.

**TREATMENT AND PROGNOSIS**

Treatment of Bartter syndrome is directed at preventing dehydration, maintaining nutritional status, and correcting hypokalemia. Potassium supplementation, often at very high doses, is required; potassium-sparing (aldosterone antagonist) diuretics may be of value. Even with appropriate therapy, serum potassium values might not normalize, particularly in patients with the neonatal form. Infants and young children require a high-sodium diet and at times sodium supplementation. Indomethacin, a prostaglandin inhibitor, can also be effective. If hypomagnesemia is present, magnesium supplementation is required. With close attention to electrolyte balance, volume status, and growth, the long-term prognosis is generally good. In a minority of patients, chronic hypokalemia, nephrocalcinosis, and chronic indomethacin therapy can lead to chronic interstitial nephritis and chronic renal failure.
531.2 Gitelman Syndrome
Rajasree Sreedharan and Ellis D. Avner

Gitelman syndrome (often called a “Bartter syndrome variant”) is a rare autosomal recessive cause of hypokalemic metabolic alkalosis, with distinct features of hypocalciuria and hypomagnesemia. Patients with Gitelman syndrome typically present in late childhood or early adulthood (see Table 531-1).

PATHOGENESIS
The biochemical features of Gitelman syndrome resemble those of chronic use of thiazide diuretics. Thiazides act on the sodium chloride cotransporter NCCT, present in the distal convoluted tubule. Through linkage analysis and mutational studies, defects in the gene encoding NCCT have been demonstrated in patients with Gitelman syndrome.

CLINICAL MANIFESTATIONS
Patients with Gitelman syndrome typically present at a later age than those with Bartter syndrome and may have symptoms similar to older children with Bartter syndrome (see Chapter 531.1). Patients often have a history of recurrent muscle cramps and spasms, presumably caused by low serum magnesium levels, nocturia, polyuria, and occasional hypotension. They usually do not have a history of recurrent episodes of dehydration. Biochemical abnormalities include hypokalemia, metabolic alkalosis, and hypomagnesemia. The urinary calcium level is usually very low (in contrast to the elevated urinary calcium level often seen in Bartter syndrome), and the urinary magnesium level is elevated. Renin and aldosterone levels are usually normal, and prostaglandin E secretion is not elevated. Growth failure is less prominent in Gitelman syndrome than in Bartter syndrome.

DIAGNOSIS
The diagnosis of Gitelman syndrome is suggested in an adolescent or adult presenting with hypokalemic metabolic alkalosis, hypomagnesemia, and hypocalciuria.

TREATMENT
Therapy is directed at correcting hypokalemia and hypomagnesemia with supplemental potassium and magnesium. Sodium supplementation or treatment with prostaglandin inhibitors is generally not necessary because patients typically do not have episodes of volume depletion or elevated prostaglandin E excretion.

531.3 Other Inherited Tubular Transport Abnormalities
Rajasree Sreedharan and Ellis D. Avner

Inherited abnormalities in distinct transporters in each segment of the nephron have now been identified and the molecular defects have been characterized. Renal tubular acidosis and nephrogenic diabetes insipidus are discussed in detail in Chapters 529 and 530, respectively. Cystinuria is an autosomal recessive disorder seen primarily in patients of Middle Eastern descent and is characterized by recurrent stone formation. The disease is caused by a defective high-affinity transporter for l-cystine and dibasic amino acids present in the proximal tubule.

Dent disease is an X-linked proximal tubulopathy with characteristic abnormalities that include low-molecular-weight proteinuria, hypercalciuria, and other features of Fanconi syndrome, such as glycosuria, aminoaciduria, and phosphaturia. Although some patients develop nephrocalcinosis, nephrolithiasis, progressive renal failure, and hypophosphatemic rickets, patients with Dent disease typically do not have proximal renal tubular acidosis or extrarenal manifestations. Loss-of-function mutations of the CLCN5 gene, which is located in Xp11.22 and encodes a renal Cl/H+ antiporter (CIC-5), are reported in patients with Dent disease. Genetic heterogeneity of Dent disease in some patients who exhibit mutations in the gene for OCRL1 (responsible for Lowe syndrome) also meets Dent disease criteria: Dent-2 disease. Dent disease includes X-linked recessive nephrolithiasis with renal failure, X-linked recessive hypophosphatemic rickets, and idiopathic low-molecular-weight proteinuria seen in Japanese children.

Mutations in an extracellular basolateral calcium-sensing receptor, normally present in the loop of Henle, can cause a dominant Bartter syndrome-like picture. These patients’ predominant symptoms are hypocalcemic and suppressed parathyroid hormone function, which differentiates them from patients with Bartter syndrome.

In the distal convoluted tubule, gain-of-function mutations in WNK1 and loss-of-function mutations in WNK4, both serine-threonine kinases, lead to excessive NCCT-mediated salt reabsorption with the clinical picture of pseudohypoaldosteronism type 2 (familial hyperkalemic hypertension, or Gordon syndrome).

In the collecting duct, gain-of-function mutations of the gene that encodes the epithelial sodium channel cause an inherited form of hypertension, Liddle syndrome. Patients with this disorder have constitutive sodium uptake in the collecting duct, with hypokalemia and suppressed aldosterone. Conversely, loss-of-function mutations cause pseudohypoaldosteronism, characterized by severe sodium wasting and hyperkalemia. A variant of the latter disorder is associated with systemic abnormalities, including defects in sweat chloride, and can resemble cystic fibrosis.

Renal hypouricemia, a defect in the SLC22A12 gene, presents with low serum uric acid levels and is complicated by exercise-induced acute renal failure. Patients have elevated urine uric acid levels and present with loin pain, nausea, and vomiting after exercise. Treatment is for acute renal failure and reducing the intensity of exercise.

Bibliography
Tubulointerstitial nephritis (TIN, also called interstitial nephritis) is the term applied to conditions characterized by tubulointerstitial inflammation and damage with relative sparing of glomeruli and vessels. Both acute and chronic primary forms exist. Interstitial nephritis can also be present with primary glomerular diseases as well as systemic diseases affecting the kidney.

**ACUTE TUBULOINTERSTITIAL NEPHRITIS**

**Pathogenesis and Pathology**

The hallmarks of acute TIN are lymphocytic infiltration of the tubulointerstitium, tubular edema, and varying degrees of tubular damage. Eosinophils may be present, particularly in drug-induced TIN; occasionally, granulomas occur. The pathogenesis is not fully understood, but a T-cell–mediated immune mechanism has been postulated. A large number of medications, especially antimicrobials, anticonvulsants, and analgesics, have been implicated as etiologic agents (Table 532-1). Other causes include infections, primary glomerular diseases, and systemic diseases such as systemic lupus erythematosus.
is invariably present, but significant hematuria or proteinuria >1.5 g/day is uncommon. One exception is patients whose TIN is caused by nonsteroidal antiinflammatory drugs (NSAIDs), who can present with the nephrotic syndrome. Urinalysis can reveal white blood cell, granular, or hyaline casts, but red blood cell casts (a characteristic of glomerular disease) are absent. The presence of urine eosinophils is neither sensitive nor specific.

Because of pyuria, the initial diagnosis may be a urinary tract infection.

Diagnosis
The diagnosis is usually based on clinical presentation and laboratory findings. A renal biopsy will establish the correct diagnosis in cases where the etiology or clinical course confounds the diagnosis. A careful history of the timing of disease onset in relation to drug exposure is essential in suspected drug-induced TIN. Because of the immune-mediated nature of TIN, signs or symptoms generally appear

Clinical Manifestations
The classic presentation of acute TIN is fever, rash, and arthralgia in the setting of a rising serum creatinine. Although the full triad may be noted in drug-induced TIN, many patients with acute TIN do not demonstrate all of the typical features. The rash can vary from maculopapular to urticarial and is often transient. Patients often have nonspecific constitutional symptoms of nausea, vomiting, fatigue, and weight loss. Flank pain may be present, presumably secondary to stretching of the renal capsule from acute inflammatory enlargement of the kidney. If acute TIN is caused by a systemic disease such as systemic lupus erythematosus, the clinical presentation will be consistent with specific signs and symptoms of the underlying disease. Unlike the typical presentation of oliguric acute renal failure seen with glomerular diseases, 30-40% of patients with acute TIN are nonoliguric, and hypertension is less common. Peripheral eosinophilia can occur, especially with drug-induced TIN. Some degree of microscopic hematuria

within 1-2 wk following exposure. In children, antimicrobials are a common inciting agent. NSAIDs are an important cause of acute TIN in children, and volume depletion or underlying chronic renal disease can increase the risk of occurrence. Urinalysis and serial measurements of serum creatinine and electrolytes should be monitored. Renal ultrasonography is not diagnostic but can demonstrate enlarged, echogenic kidneys. Removal of a suspected offending agent followed by spontaneous improvement in renal function is highly suggestive of the diagnosis, and additional testing is generally not performed in this setting. In more severe cases, in which the cause is unclear or the patient's renal function deteriorates rapidly, a renal biopsy is indicated.

**Treatment and Prognosis**

Treatment includes supportive care directed at addressing complications of acute renal failure such as hyperkalemia or volume overload (see Chapter 535.1). Corticosteroid administration within 2 wk of the discontinuation of certain offending agents (e.g., NSAIDs or antibiotics) can hasten recovery and improve the long-term prognosis in drug-induced TIN. Whether such therapy is indicated is on other causes on TIN is not clear. For patients with prolonged renal insufficiency, the prognosis remains guarded, and severe acute TIN from any cause can progress to chronic TIN.

**CHRONIC TUBULOINTERSTITIAL NEPHRITIS**

In children, chronic TIN most commonly occurs in the context of (1) an underlying congenital urologic renal disease, such as obstructive uropathy or vesicoureteral reflux, or (2) an underlying metabolic disorder affecting the kidneys (see Table 532-1). Chronic TIN can occur as an idiopathic disease, although this is more common in adults.

The juvenile nephronophthisis (JN)—medullary cystic kidney disease complex (MCKD) is a group of inherited, genetically determined cystic renal diseases that share the common histologic finding of chronic TIN. At least 15 different genes are associated with JN, usually inherited as an autosomal recessive disease. These genes only define 30% of cases, and new genes are being identified at a rapid pace. Although uncommon in the United States, JN causes 10-20% of pediatric end-stage renal disease (ESRD) in Europe. Patients with JN typically present with polyuria, growth failure, unexplained anemia, and chronic renal failure in late childhood or adolescence. As a ciliopathy, JN is often associated with extrarenal features such as retinal degeneration, hepatobiliary disease, cerebellar vermis hypoplasia, laterality defects, intellectual disability, and shortening of bones. These features are represented in a number of syndromes, such as Senior-Løken syndrome (retinitis pigmentosa), Joubert syndrome (cerebellar vermis hypoplasia), Bardet-Biedel syndrome (intellectual disability, obesity), and Jeune asphyxiating thoracic dystrophy (shortening of the long bones, narrow rib cage), and many others. MCKD is an autosomal dominant disease that typically manifests in adulthood. TIN with uveitis is a rare autoimmune syndrome of chronic TIN with anterior uveitis and bone marrow granulomas that occurs primarily in adolescent girls. Chronic TIN is seen in all forms of progressive renal disease, regardless of the underlying cause, and the severity of interstitial disease is the single most important factor predicting progression to ESRD.

**Pathogenesis and Pathology**

The pathophysiology of chronic TIN is undefined, but data suggest that, in addition to abnormal cilia structure and function in JN and MCKD, it is immune mediated. Cells making up the interstitial infiltrate appear to be a combination of native interstitial cells, inflammatory cells recruited from the circulation, and resident tubular cells that undergo epithelial-mesenchymal transformation. Grossly, kidneys can appear pale and small for age. Microscopically, tubular atrophy and "dropout" with interstitial fibrosis and a patchy lymphocytic interstitial inflammation are seen. Patients with JN often have characteristic small cysts in the corticomedullary region. In primary chronic TIN, glomeruli are relatively spared until late in the disease course. Patients with chronic TIN secondary to a primary glomerular disease have histologic evidence of the primary disease.

**Clinical Manifestations**

The clinical features of chronic TIN are often nonspecific and can reflect signs and symptoms of renal insufficiency (see Chapter 535). Fatigue, growth failure, polyuria, polydipsia, and enuresis are often present. Anemia that is seemingly disproportionate to the degree of renal insufficiency is common and is a particularly prominent feature in JN. Because tubular damage often leads to renal salt wasting, significant hypertension is unusual. Fanconi syndrome, proximal renal tubular acidosis, distal renal tubular acidosis, and hyperkalemic distal renal tubular acidosis can occur.

**Diagnosis**

The diagnosis is suggested by signs or symptoms of renal tubular damage such as polyuria and an elevated serum creatinine value, coupled with a history suggestive of a chronic disease, such as long-standing enuresis or the presence of anemia resistant to iron therapy. Radiographic studies, in particular ultrasonography, can give additional evidence of chronicity, such as small, echogenic kidneys, cortical microcysts suggesting JN, or findings of obstructive uropathy. A vesicocystourethrogram can demonstrate the presence of vesicoureteral reflux or bladder abnormalities. If JN is suspected, molecular diagnosis is available. In instances in which the cause is unclear, a renal biopsy may be performed. In cases of advanced disease, a renal biopsy might not be diagnostic. Many end-stage kidney diseases display a common histologic appearance of tubular fibrosis and inflammation.

**Treatment and Prognosis**

Therapy is directed at maintaining fluid and electrolyte balance and avoiding further exposure to nephrotoxic agents. Patients with obstructive uropathies can require salt supplementation and treatment with potassium-binding resin (Kayexalate). Prevention of infection by antibiotic prophylaxis can slow progression of renal damage in appropriate patients. Prognosis in patients with chronic TIN depends in large part on the nature of the underlying disease. Patients with obstructive uropathy or vesicoureteral reflux can have a variable degree of renal damage and thus a variable course. ESRD can develop over mo to years. Patients with JN uniformly progress to ESRD by adolescence. Patients with metabolic disorders can benefit from treatment when available.

Bibliography
Aberrant renal function often results from purposeful or accidental exposure to any number of agents that are potential or actual nephrotoxins. Iodinated radiocontrast agents are generally well tolerated by most patients without significant adverse consequences. In volume-depleted patients or patients with underlying chronic kidney
disease, their use poses a serious risk for the development of acute kidney injury with significant attendant morbidity and mortality. Bio-
logic nephrotoxins include venemous exposures from insects, reptiles, amphibians, and a wide variety of sea-dwelling animals. The most common forms of toxic nephropathy unfortunately relate to the exposure of children to pharmacologic agents, accounting for close to 20% of episodes of acute kidney injury occurring in children and adoles-
cents. Age, underlying medical condition, including surgical exposure, genetics, exposure dose, and the concomitant use of other drugs all influence the likelihood of developing acute kidney injury.

Table 533-1 summarizes the agents that commonly cause acute kidney injury and some of their clinical manifestations. Mechanisms

of injury often help to explain the presentation; multiple toxic exposures in patients with complicated clinical histories often limit the ability to clearly establish clinical cause and effect. For example, diminished urine output may be the clinical hallmark of tubular obstruction caused by agents such as methotrexate or agents that cause acute tubular necrosis, such as amphotericin B or pentamidine. Alternatively, nephrogenic diabetes insipidus may be the critical clinical manifestation of agents that cause interstitial nephritis, such as lithium or cisplatin. Nephrotoxicity is often reversible if the noxious agent is promptly removed.

Clinical use of potential nephrotoxins should be used judiciously. Necessity of exposure, dosing parameters, and the use of drug levels or pharmacogenomic data, when available, should always be considered. Caution is particularly mandated for patients with complex medical conditions that include preexisting renal disease, cardiac disease, diabetes, and/or complicated surgeries. Alternative approaches to imaging, or use of different pharmacologic options should be considered when possible. Imaging modalities such as ultrasonography, radionuclide scanning, or magnetic resonance imaging may be preferable to contrast studies in some patients. Alternatively, judicious volume expansion with or without the administration of N-acetylcysteine might offer renoprotection when radioiodinated contrast studies are critical. Pharmacologic agents with no known renal effects can often be substituted for known nephrotoxins with equal clinical efficacy. In all cases, simultaneous use of known nephrotoxins should be avoided whenever necessary.

Bibliography is available at Expert Consult.
**Bibliography**

Renal cortical necrosis is a rare cause of acute renal failure occurring secondary to extensive ischemic damage of the renal cortex. It occurs most commonly in neonates and in adolescents of childbearing age (see Chapter 535).

ETIOLOGY
In newborns, cortical necrosis is most commonly associated with hypoxic or ischemic insults caused by perinatal asphyxia, placental abruption, and twin–twin or fetal–maternal transfusion. Other causes include renal vascular thrombosis and severe congenital heart disease. After the neonatal period, cortical necrosis is most commonly seen in children with septic shock or severe hemolytic-uremic syndrome. In adolescents and women, cortical necrosis occurs in association with obstetric complications including prolonged intrauterine fetal death, placental abruption, or amniotic fluid embolism.

Less-common causes of cortical necrosis include malaria, extensive burns, snakebites, infectious endocarditis, and medications (e.g., non-steroidal antiinflammatory agents). Acute renal cortical necrosis has also been reported to occur in systemic lupus erythematosus–associated antiphospholipid antibody syndrome.

CLINICAL MANIFESTATIONS
Cortical necrosis clinically presents as acute renal failure in patients with predisposing causes. Urine output is diminished and gross and/or microscopic hematuria may be present. Hypertension is common, and thrombocytopenia may be present as a result of renal microvascular injury.

LABORATORY AND RADIOLOGIC FINDINGS
Laboratory results are consistent with acute renal failure: an elevated blood urea nitrogen and creatinine, hyperkalemia, and metabolic acidosis. Anemia and thrombocytopenia are common. Urinalysis reveals hematuria and proteinuria.

Ultrasound examination with Doppler flow studies or CT scan demonstrates decreased perfusion to both kidneys. A radionuclide renal scan shows decreased uptake with significantly delayed or absent function.

TREATMENT
It is important to prevent or treat the underlying cause of acute cortical necrosis, when possible. Therapy involves medical management of acute renal failure, often with the initiation of dialysis as indicated. Management is otherwise supportive and involves volume repletion, correction of asphyxia, and treatment of sepsis.

PROGNOSIS
Untreated, renal cortical necrosis has a high mortality rate. Twenty to 40% of patients have partial recovery of renal function, the extent of which depends on the amount of preserved cortical tissue. All patients require long-term follow-up for chronic kidney disease.

Bibliography is available at Expert Consult.
Bibliography
Acute kidney injury (AKI), formerly called acute renal failure, is a clinical syndrome in which a sudden deterioration in renal function results in the inability of the kidneys to maintain fluid and electrolyte homeostasis. AKI occurs in 2-3% of children admitted to pediatric tertiary care centers and in as many as 8% of infants in neonatal intensive care units. A classification system has been proposed to standardize the definition of AKI in adults. These criteria of risk, injury, failure, loss, and end-stage renal disease were given the acronym of RIFLE. A modified RIFLE criteria (pRIFLE) was developed to characterize the pattern of AKI in critically ill children (Table 535-1). Because RIFLE focuses on the glomerular filtration rate (GFR), a modification (Acute Kidney Injury Network) categorizes severity by rise in serum creatinine: stage I >150%, stage II >200%, stage III >300%.

### PATHOGENESIS
AKI has been conventionally classified into 3 categories: prerenal, intrinsic renal, and postrenal (Table 535-2 and Fig. 535-1).
Prerenal AKI, also called *prerenal azotemia*, is characterized by diminished effective circulating arterial volume, which leads to inadequate renal perfusion and a decreased GFR. Evidence of kidney damage is absent. Common causes of prerenal AKI include dehydration, sepsis, hemorrhage, severe hypoalbuminemia, and cardiac failure. If the underlying cause of the renal hypoperfusion is reversed promptly, renal function returns to normal. If hypoperfusion is sustained, intrinsic renal parenchymal damage can develop.

Intrinsic renal AKI includes a variety of disorders characterized by renal parenchymal damage, including sustained hypoperfusion and ischemia. Many forms of *glomerulonephritis*, including postinfectious glomerulonephritis, lupus nephritis, Henoch-Schönlein purpura nephritis, membranoproliferative glomerulonephritis, and anti-glomerular basement membrane nephritis, can cause AKI. Ischemic/hypoxic injury and nephrotoxic insults are the most common causes of intrinsic AKI in the United States, and are more common with an underlying comorbid condition; most are associated with cardiac, oncologic, urologic, renal, and genetic disorders or prematurity. Severe and prolonged ischemic/hypoxic injury and nephrotoxic insult lead to *acute tubular necrosis* (ATN), seen most often in critically ill infants and children. Mechanisms leading to ischemic AKI include hypotension/intravascular volume depletion (hemorrhage, third-space fluid losses, diarrhea), decreased effective intravascular volume (heart failure, cirrhosis, hepatorenal syndrome, peritonitis, abdominal compartment syndrome), vasodilation/vasoconstriction (sepsis, hepatorenal syndrome), renal artery obstruction (thrombosis, embolization, stenosis), intrarenal artery disease (vasculitis, hemolytic-uremic syndrome, sickle cell anemia, transplant rejection), and impaired renal blood flow (cyclosporine, tacrolimus, angiotensin-converting enzyme [ACE] inhibitors, angiotensin-receptor blocking agents, radiopaque contrast agents).

The typical pathologic feature of ATN is tubular cell necrosis, although significant histologic changes are not consistently seen in patients with clinical ATN. The mechanisms of injury in ATN can include alterations in intrarenal hemodynamics, tubular obstruction, and passive backleak of the glomerular filtrate across injured tubular cells into the peritubular capillaries.

Tumor lysis syndrome is a specific form of AKI related to spontaneous or chemotherapy-induced cell lysis in patients with lymphoproliferative malignancies. This disorder is primarily caused by obstruction of the tubules by uric acid crystals (see Chapters 495 and 496). *Acute interstitial nephritis* is another common cause of AKI and is usually a result of a hypersensitivity reaction to a therapeutic agent or various infectious agents (see Chapter 532).

Postrenal AKI includes a variety of disorders characterized by obstruction of the urinary tract. In neonates and infants, congenital conditions, such as posterior urethral valves and bilateral ureteropelvic junction obstruction, account for the majority of cases of AKI. Other conditions, such as urolithiasis, tumor (intraabdominal lesion or within the urinary tract), hemorrhagic cystitis, and neurogenic bladder, can cause AKI in older children and adolescents. In a patient with 2 functioning kidneys, obstruction must be bilateral to result in AKI. Relief of the obstruction usually results in recovery of renal function, except in patients with associated renal dysplasia or prolonged urinary tract obstruction.

**CLINICAL MANIFESTATIONS AND DIAGNOSIS**
A carefully taken history is critical in defining the cause of AKI. An infant with a 3 day history of vomiting and diarrhea most likely has prerenal AKI caused by volume depletion, but hemolytic-uremic syndrome (HUS) must be a consideration. A 6 yr old child with a recent pharyngitis who presents with periorbital edema, hypertension, and gross hematuria most likely has intrinsic AKI related to acute postinfectious glomerulonephritis. A critically ill child with a history of protracted hypotension or with exposure to nephrotoxic medications most likely has ATN. A neonate with a history of hydrenephrosis on prenatal ultrasound and a palpable bladder most likely has congenital urinary tract obstruction, probably related to posterior urethral valves.

The physical examination must be thorough, with careful attention to volume status. Tachycardia, dry mucous membranes, and poor peripheral perfusion suggest an inadequate circulating volume and the possibility of prerenal AKI (see Chapter 57). Hypertension, peripheral edema, rales, and a cardiac gallop suggest volume overload and the possibility of intrinsic AKI from glomerulonephritis or ATN. The presence of a rash and arthritis might indicate systemic lupus erythematosus (SLE) or Henoch-Schönlein purpura nephritis. Palpable flank masses may be seen with renal vein thrombosis, tumors, cystic disease, or urinary tract obstruction.

**LABORATORY FINDINGS**
Laboratory abnormalities can include anemia (the anemia is usually dilutional or hemolytic, as in SLE, renal vein thrombosis,
HUS); leukopenia (SLE, sepsis); thrombocytopenia (SLE, renal vein thrombosis, sepsis, HUS); hyponatremia (dilutitional); metabolic acidosis; elevated serum concentrations of blood urea nitrogen, creatinine, uric acid, potassium, and phosphate (diminished renal function); and hypocalcemia (hyperparathyroidism).

The serum C3 level may be depressed (postinfectious glomerulonephritis, SLE, or membranoproliferative glomerulonephritis), and antibodies may be detected in the serum to streptococcal (poststreptococcal glomerulonephritis), nuclear (SLE), neutrophil cytoplasmic (granulomatosis with polyangiitis, microscopic polyarteritis), or glomerular basement membrane (Goodpasture disease) antigens.

The presence of hematuria, proteinuria, and red blood cell or granular urinary casts suggests intrinsic AKI, in particular glomerular disease and ATN. The presence of white blood cells and white blood cell casts with low-grade hematuria and proteinuria suggests tubulointerstitial disease. Urinary eosinophils may be present in children with drug-induced tubulointerstitial nephritis.

Urinary indices may be useful in differentiating prerenal AKI from intrinsic AKI (Table 535-3). Patients whose urine shows an elevated specific gravity (>1.020), elevated urine osmolality (UOsm > 500 mOsm/kg), low urine sodium (UNa < 20 mEq/L), and fractional excretion of sodium <1% (<2.5% in neonates) most likely have prerenal AKI. Those with a specific gravity of <1.010, low urine osmolality (UOsm < 350 mOsm/kg), high urine sodium (UNa > 40 mEq/L), and fractional excretion of sodium >2% (>10% in neonates) most likely have intrinsic AKI.

Chest radiography may reveal cardiomegaly, pulmonary congestion (fluid overload), or pleural effusions. Renal ultrasonography can reveal hydronephrosis and/or hydroureter, which suggest urinary tract obstruction, or nephromegaly, consistent with intrinsic renal disease. Renal biopsy can ultimately be required to determine the precise cause of AKI in patients who do not have clearly defined prerenal or postrenal AKI.

Although serum creatinine is used to measure kidney function, it is an insensitive and delayed measure of decreased kidney function following AKI. Other biomarkers under investigation include changes in plasma neutrophil gelatinase–associated lipocalin and cystatin C levels and urinary changes in neutrophil gelatinase–associated lipocalin, interleukin 18, and kidney injury molecule-1.

**TREATMENT**

**Medical Management**

In infants and children with urinary tract obstruction, such as in a newborn with suspected posterior urethral valves, a bladder catheter should be placed immediately to ensure adequate drainage of the urinary tract. The placement of a bladder catheter may also be considered in nonambulatory older children and adolescents to accurately monitor urine output during AKI; however, precautions to prevent iatrogenic infection should be taken.

**TREATMENT**

**Medical Management**

In infants and children with urinary tract obstruction, such as in a newborn with suspected posterior urethral valves, a bladder catheter should be placed immediately to ensure adequate drainage of the urinary tract. The placement of a bladder catheter may also be considered in nonambulatory older children and adolescents to accurately monitor urine output during AKI; however, precautions to prevent iatrogenic infection should be taken.

**Diuretic therapy** should be considered only after the adequacy of the circulating blood volume has been established. Furosemide (2-4 mg/kg) and mannitol (0.5 g/kg) may be administered as a single IV dose. Bumetanide (0.1 mg/kg) may be given as an alternative to furosemide. If urine output is not improved, then a continuous diuretic infusion may be considered. To increase renal cortical blood flow, many clinicians administer dopamine (2-3 µg/kg/min) in conjunction with diuretic therapy, although no controlled data support this practice. There is little evidence that diuretics or dopamine can prevent AKI or hasten recovery. Mannitol may be effective in prevention of pigment (myoglobin, hemoglobin)-induced renal failure. Atrial natriuretic peptide may be of value in preventing or treating AKI, although there is little pediatric evidence to support its use.

If there is no response to a diuretic challenge, diuretics should be discontinued and fluid restriction is essential. Patients with a relatively normal intravascular volume should initially be limited to 400 mL/m²/24 hr (insensible losses) plus an amount of fluid equal to the urine output for that day. Extrarenal (blood, gastrointestinal tract) fluid losses should be replaced, milliliter for milliliter, with appropriate fluids. Markedly hypervolemic patients can require further fluid restriction, omitting the replacement of insensible fluid losses, urine output, and extrarenal losses to diminish the expanded intravascular volume. Fluid intake, urine and stool output, body weight, and serum chemistries should be monitored on a daily basis.

In AKI, rapid development of hyperkalemia (serum potassium level > 6 mEq/L) can lead to cardiac arrhythmia, cardiac arrest, and death. The earliest electrocardiographic change seen in patients with developing hyperkalemia is the appearance of peaked T waves. This may be followed by widening of the QRS intervals, ST segment depression, ventricular arrhythmias, and cardiac arrest (see Chapter 55.4).

*The sensitivity and specificity of urine sodium of <20 mEq/L in differentiating prerenal azotemia from acute tubular necrosis are 96% and 82%, respectively.
†Fractional excretion of sodium is the urine:plasma (U:P) ratio of sodium divided by U:P of creatinine.

Procedures to deplete body potassium stores should be initiated when the serum potassium value rises to >6.0 mEq/L. Exogenous sources of potassium (dietary, intravenous fluids, total parenteral nutrition) should be eliminated. Sodium polystyrene sulfonate resin (Kayexalate), 1 g/kg, should be given orally or by retention enema. This resin exchanges sodium for potassium and can take several hr to take effect. A single dose of 1 g/kg can be expected to lower the serum potassium level by about 1 mEq/L. Resin therapy may be repeated every 2 hr, the frequency being limited primarily by the risk of sodium overload.

More severe elevations in serum potassium (>7 mEq/L), especially if accompanied by electrocardiographic changes, require emergency measures in addition to Kayexalate. The following agents should be administered:

- **Calculus glonatone 10% solution, 1.0 mL/kg IV, over 3-5 min**
- **Sodium bicarbonate, 1-2 mEq/kg IV, over 5-10 min**
- **Regular insulin, 0.1 units/kg, with glucose 50% solution, 1 mL/kg, over 1 hr**

Calcium gluconate counteracts the potassium-induced increase in myocardial irritability but does not lower the serum potassium level. Administration of sodium bicarbonate, insulin, or glucose lowers the serum potassium level by shifting potassium from the extracellular to the intracellular compartment. A similar effect has been reported with the acute administration of β-adrenergic agonists in adults, but there are no controlled data in pediatric patients. Because the duration of action of these emergency measures is just a few hours, persistent hyperkalemia should be managed by dialysis.

**Mild metabolic acidosis** is common in AKI because of retention of hydrogen ions, phosphate, and sulfate, but it rarely requires treatment. If acidosis is severe (arterial pH < 7.15; serum bicarbonate < 8 mEq/L) or contributes to significant hyperkalemia, treatment is indicated. The acidosis should be corrected partially by the intravenous route, generally giving enough bicarbonate to raise the arterial pH to 7.20 (which approximates a serum bicarbonate level of 12 mEq/L). The remainder of the correction may be accomplished by oral administration of sodium bicarbonate after normalization of the serum calcium and phosphorus levels. Correction of metabolic acidosis with intravenous bicarbonate can precipitate tetany in patients with renal failure as rapid correction of acidosis reduces the ionized calcium concentration (see Chapter 55).

**Hypocalcemia** is primarily treated by lowering the serum phosphorus level. Calcium should not be given intravenously, except in cases of tetany, to avoid deposition of calcium salts into tissues. Patients should be instructed to follow a low-phosphorus diet, and phosphate binders should be orally administered to bind any ingested phosphate and increase GI phosphate excretion. Common agents include sevelamer (Renagel), calcium carbonate (Tums tablets or Tritalac suspension), and calcium acetate (PhosLo). Aluminum-based binders, commonly employed in the past, should be avoided because of the risk of aluminum toxicity.

**Hypokalemia** is most commonly a dilutional disturbance that must be corrected by fluid restriction rather than sodium chloride administration. Administration of hypertonic (3%) saline should be limited to patients with symptomatic hypokalemia (seizures, lethargy) or those with a serum sodium level <120 mEq/L. Acute correction of the serum sodium to 125 mEq/L (mmol/L) should be accomplished using the following formula:

\[
\text{mEq sodium required} = 0.6 \times \text{weight in kg} \times (125 - \text{serum sodium in mEq/L})
\]

AKI patients are predisposed to GI bleeding because of uremic platelet dysfunction, increased stress, and heparin exposure if treated with hemodialysis or continuous renal replacement therapy. Oral or intravenous H₂ blockers such as ranitidine are commonly administered to prevent this complication.

**Hypertension** can result from hyperreninemia associated with the primary disease process and/or expansion of the extracellular fluid volume and is most common in AKI patients with acute glomerulonephritis or HUS. Salt and water restriction is critical, and diuretic administration may be useful (see Chapter 445). Isradipine (0.05-0.15 mg/kg/dose, maximum dose 5 mg qid) may be administered for relatively rapid reduction in blood pressure. Longer-acting agents such as calcium channel blockers (amlodipine, 0.1-0.6 mg/kg/24 hr qd or divided bid) or β blockers (propranolol, 0.5-8.0 mg/kg/24 hr divided bid or tid; labetalol, 4-40 mg/kg/24 hr divided bid or tid) may be helpful in maintaining control of blood pressure. Children with severe symptomatic hypertension (hypertensive urgency or emergency) should be treated with continuous infusions of nicardipine (0.5-5.0 µg/kg/min), sodium nitroprusside (0.5-10.0 µg/kg/min), or esmolol (150-300 µg/kg/min) and converted to intermittently dosed antihypertensives when more stable.

**Neurologic symptoms** in AKI can include headache, seizures, lethargy, and confusion (encephalopathy). Potential etiologic factors include hypertensive encephalopathy, hypokalemia, hypocalcemia, cerebral hemorrhage, cerebral vasculitis, and the uremic state. Benzodiazepines are the most effective agents in acutely controlling seizures, and subsequent therapy should be directed toward the precipitating cause.

The anemia of AKI is generally mild (hemoglobin 9-10 g/dL) and primarily results from volume expansion (hemodilution). Children with HUS, SLE, active bleeding, or prolonged AKI can require transfusion of packed red blood cells if their hemoglobin level falls below 7 g/dL. In hypervolemic patients, blood transfusion carries the risk of further volume expansion, which can precipitate hypertension, heart failure, and pulmonary edema. Slow (4-6 hr) transfusion with packed red blood cells (10 mL/kg) diminishes the risk of hypervolemia. The use of fresh, washed red blood cells minimizes the acute risk of hyperkalemia, and the chronic risk of sensitization if the patient becomes a future candidate for renal replacement therapy. In the presence of severe hypervolemia or hyperkalemia, blood transfusions are most safely administered during dialysis or ultrafiltration.

**Nutrition** is of critical importance in children who develop AKI. In most cases, sodium, potassium, and phosphorus should be restricted. Protein intake should be moderately restricted while maximizing caloric intake to minimize the accumulation of nitrogenous wastes. In critically ill patients with AKI, parenteral hyperalimentation with essential amino acids should be considered.

**Dialysis**

Indications for dialysis in AKI include the following:

- Anuria/oliguria
- Volume overload with evidence of hypertension and/or pulmonary edema refractory to diuretic therapy
- Persistent hyperkalemia
- Severe metabolic acidosis unresponsive to medical management
- Uremia (encephalopathy, pericarditis, neuropathy)
- Blood urea nitrogen >100-150 mg/dL (or lower if rapidly rising)
- Calcium/phosphorus imbalance, with hypocalcemic tetany that cannot be controlled by other measures

An additional indication for dialysis is the inability to provide adequate nutritional intake because of the need for severe fluid restriction. In patients with AKI, dialysis support may be necessary for days or for up to 12 wk. Many patients with AKI require dialysis support for 1-3 wk. Table 535-4 lists the advantages and disadvantages of the 3 types of dialysis.

**Intermittent hemodialysis** is useful in patients with relatively stable hemodynamic status. This highly efficient process accomplishes both fluid and electrolyte removal in 3-4 hr sessions using a pump-driven extracorporeal circuit and large central venous catheter. Intermittent hemodialysis may be performed 3-7 times per week based on the patient's fluid and electrolyte balance.

**Peritoneal dialysis** is most commonly employed in neonates and infants with AKI, although this modality may be used in children and adolescents of all ages. Hypersmolar dialysate is infused into the peritoneal cavity via a surgically or percutaneously placed peritoneal dialysis catheter. The fluid is allowed to dwell for 45-60 min and is then drained from the patient by gravity (manually or with the use of machine-driven cycling), accomplishing fluid and electrolyte removal. Cycles are repeated for 8-24 hr/day based on the patient's
fluid and electrolyte balance. Anticoagulation is not necessary. Peritoneal dialysis is contraindicated in patients with significant abdominal pathology.

Continuous renal replacement therapy (CRRT) is useful in patients with unstable hemodynamic status, concomitant sepsis, or multiorgan failure in the intensive care setting. CRRT is an extracorporeal therapy in which fluid, electrolytes, and small- and medium-size solutes are continuously removed from the blood (24 hr/day) using a specialized pump-driven machine. Usually, a double-lumen catheter is placed into the subclavian, internal jugular, or femoral vein. The patient is then connected to the pump-driven CRRT circuit, which continuously passes the patient’s blood across a highly permeable filter.

CRRT may be performed in 3 basic fashions. In continuous venovenous hemofiltration, a large volume of fluid is driven by systemic or pump-assisted pressure across the filter, bringing with it by convection other molecules such as urea, creatinine, phosphorus, and uric acid. The blood volume is reconstituted by IV infusion of a replacement fluid having a desirable electrolyte composition similar to that of blood. Continuous venovenous hemofiltration dialysis uses the principle of diffusion by circulating dialysate in a countercurrent direction on the ultrafiltrate side of the membrane. No replacement fluid is used. Continuous hemodiafiltration employs both replacement fluid and dialysate, offering the most effective solute removal of all forms of CRRT.

Table 535-4 compares the relative risks and benefits of the various renal replacement therapies.

**PROGNOSIS**

The mortality rate in children with AKI is variable and depends entirely on the nature of the underlying disease process rather than on the renal failure itself. Children with AKI caused by a renal-limited condition have a very low mortality rate (<1%); those with AKI related to multiorgan failure have a very high mortality rate (>90%).

The prognosis for recovery of renal function depends on the disorder that precipitated AKI. Recovery of renal function is likely after AKI resulting from prerenal causes ATN, acute interstitial nephritis, or tumor lysis syndrome. Recovery of renal function is unusual when AKI results from most types of rapidly progressive glomerulonephritis, bilateral renal vein thrombosis, or bilateral cortical necrosis. Medical management may be necessary for a prolonged period to treat the sequelae of AKI, including chronic renal insufficiency, hypertension, renal tubular acidosis, and urinary concentrating defect.

### 535.2 Chronic Kidney Disease

**Rajasree Sreedharan and Ellis D. Avner**

Chronic kidney disease (CKD) is determined by the presence of kidney damage and level of kidney function (GFR), irrespective of diagnosis. The stage of the CKD is assigned based on the level of kidney function (Tables 535-5 and 535-6). The prevalence of CKD in the pediatric population is approximately 18 per 1 million. The prognosis for the infant, child, or adolescent with CKD has improved dramatically since the 1970s because of improvements in medical management (aggressive nutritional support, recombinant erythropoietin, recombinant growth hormone), dialysis techniques, and kidney transplantation.

**ETIOLOGY**

In children, CKD may be the result of congenital, acquired, inherited, or metabolic renal disease, and the underlying cause correlates closely with the age of the patient at the time when CKD is first detected. CKD in children <5 yr old is most commonly a result of congenital abnormalities such as renal hypoplasia, dysplasia, or obstructive uropathy. Additional causes include congenital nephrotic syndrome, prune belly syndrome, cortical necrosis, focal segmental glomerulosclerosis, autosomal recessive polycystic kidney disease, renal vein thrombosis, and HUS.

After 5 yr of age, acquired diseases (various forms of glomerulonephritis including lupus nephritis) and inherited disorders (familial

juvenile nephropathies (e.g., Alport syndrome) predominate. CKD related to metabolic disorders (cystinosis, hyperoxaluria) and certain inherited disorders (both autosomal dominant and recessive polycystic kidney disease) can occur throughout the childhood years.

**PATHOGENESIS**

In addition to progressive injury with ongoing structural or metabolic genetic diseases, renal injury can progress despite removal of the original insult.

**Hyperfiltration injury** may be an important final common pathway of glomerular destruction, independent of the underlying cause of renal injury. As nephrons are lost, the remaining nephrons undergo structural and functional hyperfiltration characterized by an increase in glomerular blood flow. The driving force for glomerular filtration is thereby increased in the surviving nephrons. Although this compensatory hyperfiltration temporarily preserves total renal function, it can cause progressive damage to the surviving glomeruli, possibly by a direct effect of the elevated hydrostatic pressure on the integrity of the capillary wall and/or the toxic effect of increased protein traffic across the capillary wall. Over time, as the population of sclerosed nephrons increases, the surviving nephrons suffer an increased excretory burden, resulting in a vicious cycle of increasing glomerular blood flow and hyperfiltration injury.

**Proteinuria** itself can contribute to renal functional decline. Proteins that traverse the glomerular capillary wall can exert a direct toxic effect on tubular cells and recruit monocytes and macrophages, enhancing the process of glomerular sclerosis and tubulointerstitial fibrosis. Uncontrolled hypertension can exacerbate disease progression by causing arteriolar nephrosclerosis and by increasing the hyperfiltration injury.

**Hyperphosphatemia** can increase progression of disease by leading to calcium phosphate deposition in the renal interstitium and blood vessels. Hyperlipidemia, a common condition in CKD patients, can adversely affect glomerular function through oxidant-mediated injury.

CKD may be viewed as a continuum of disease, with increasing biochemical and clinical manifestations as renal function deteriorates. Regardless of etiology, the progression of tubulointerstitial fibrosis is the primary determinant of progression of CKD. Table 535-7 outlines the pathophysiologic manifestations of CKD. End-stage renal disease (ESRD) is an administrative term in the United States; it is used to define all patients who are treated with dialysis or kidney transplantation. Patients with ESRD are a subset of the patients with stage 5 CKD.

**CLINICAL MANIFESTATIONS**

The clinical presentation of CKD is varied and depends on the underlying renal disease. Children and adolescents with CKD from chronic glomerulonephritis can present with edema, hypertension, hematuria, and proteinuria. Infants and children with congenital disorders such as renal dysplasia and obstructive uropathy can present in the neonatal period with failure to thrive, polyuria, dehydration, urinary tract infection, or overt renal insufficiency. Congenital kidney disease is diagnosed with prenatal ultrasonography in many infants, allowing early diagnostic and possible therapeutic intervention. Children with familial juvenile nephropathies can have a very subtle presentation with nonspecific complaints such as headache, fatigue, lethargy, anorexia, vomiting, polydipsia, polyuria, and growth failure over a number of years.

The physical examination in patients with CKD can reveal pallor and a sallow appearance. Patients with long-standing untreated CKD can have short stature and the bony abnormalities of renal osteodystrophy (see Chapter 529.4). Children with CKD caused by chronic glomerulonephritis (or children with advanced renal failure from any cause) can have edema, hypertension, and other signs of extracellular fluid volume overload.

**LABORATORY FINDINGS**

Laboratory findings can include elevations in blood urea nitrogen and serum creatinine and can reveal hyperkalemia, hyponatremia (if volume overloaded), hypernatremia (loss of free water), acidosis, hypocalcemia, hyperphosphatemia, and an elevation in uric acid. Patients with heavy proteinuria can have hypoalbuminemia. A complete blood cell count may show a normochromic, normocytic anemia.

Serum cholesterol and triglyceride levels are often elevated. In children with CKD caused by glomerulonephritis, the urinalysis shows hematuria and proteinuria. In children with CKD from congenital lesions

</table>
such as renal dysplasia, the urinalysis usually has a low specific gravity and minimal abnormalities by dipstick or microscopy.

Insulin clearance is the gold standard to determine GFR, but it is not easy to measure. Endogenous creatinine clearance is the most widely used marker of GFR, but creatinine secretion falsely elevates the calculated GFR. Several other markers are under investigation to accurately determine GFR in children, such as cystatin C and iohexol. In children age 1-16 yr, the degree of renal dysfunction may be determined by applying a new bedside formula that estimates GFR between 15 and 75 mL/min/1.73 m²: estimated GFR = 0.43 \times height in cm/serum creatinine in mg/dL.

**TREATMENT**

The treatment of CKD is aimed at replacing absent or diminished renal functions, which progressively deteriorate in parallel with the progressive loss of GFR, and slowing the progression of renal dysfunction. Children with CKD should be treated at a pediatric center capable of supplying multidisciplinary services, including medical, nursing, social service, nutritional, and psychological support.

The management of CKD requires close monitoring of a patient’s clinical and laboratory status. Blood studies to be followed routinely include serum electrolytes, blood urea nitrogen, creatinine, calcium, phosphorus, albumin, alkaline phosphatase, and hemoglobin levels. Periodic measurement of intact parathyroid hormone (PTH) levels and roentgenographic studies of bone may be of value in detecting early evidence of renal osteodystrophy. Echocardiography should be performed periodically to identify left ventricular hypertrophy and cardiac dysfunction that can occur as a consequence of the complications of CKD.

**Nutrition**

Nutritional management by a dietician experienced in pediatric renal patients is recommended by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF KDOQI). Counseling based on individualized assessment should be considered for all children and their families with CKD stages 2 to 5 and 5D. Patients should receive 100% of estimated energy requirement for age, individually adjusted for physical activity level, body mass index, and response in rate of weight gain or loss. When oral supplemental nutrition with increased calories or fluid volume is insufficient, tube feeding should be considered. Calories should be balanced between carbohydrate, unsaturated fat in physiological ranges (per dietary reference intake [DRI]), and protein. Protein intake recommendation is 100-140% of the DRI for ideal weight for children with stage 3 CKD, 100-120% of the DRI in stages 4 and 5 CKD, and 100% with allowance for dialysis loss in CKD stage 5D, with use of commercial supplements as needed. Children with CKD stages 2-5 should receive 100% of DRI of vitamins and trace elements; water-soluble vitamin supplements are often required in CKD stage 5D.

**Renal Osteodystrophy**

The term renal osteodystrophy is used to indicate a spectrum of bone disorders seen in patients with CKD. The most common condition seen in children is high-turnover bone disease caused by secondary hyperparathyroidism. The skeletal pathologic finding in this condition is osteitis fibrosa cystica.

The pathophysiology of renal osteodystrophy is complex. Early in the course of CKD, when the GFR declines to approximately 50% of normal, the decrease in functional kidney mass leads to a decline in renal 1α-hydroxylase activity, with decreased production of activated vitamin D (1,25-dihydroxycalciferol). This deficiency in activated vitamin D results in decreased intestinal calcium absorption, hypocalcemia, and increased parathyroid gland activity. Excessive PTH secretion attempts to correct the hypocalcaemia by increasing bone resorption. Later in the course of CKD, when the GFR declines to 20-25% of normal, compensatory mechanisms that have been operative to enhance renal phosphate excretion become inadequate, resulting in hyperphosphatemia, which further promotes hypocalcemia and increased PTH secretion.

Clinical manifestations of renal osteodystrophy include muscle weakness, bone pain, and fractures with minor trauma. In growing children, rachitic changes, varus and valgus deformities of the long bones, and slipped capital femoral epiphyses may be seen. Laboratory studies can demonstrate a decreased serum calcium level and increased serum phosphorus, alkaline phosphatase, and PTH levels. Radiographs of the hands, wrists, and knees show subperiosteal resorption of bone with widening of the metaphyses.

The goals of treatment are to prevent bone deformity and normalize growth velocity using both dietary and pharmacologic interventions. The target phosphorus level for adolescents is between 3.5 and 5.5 mg/dL, and for children 1-12 yr of age it is 4-6 mg/dL. Children and adolescents should follow a low-phosphorus diet, and infants should be provided with a low-phosphorus formula such as Similac PM 60/40. It is impossible to fully restrict phosphorus intake, and so phosphate binders are used to enhance GI phosphate excretion. Although calcium-based binders have historically been the most commonly used, non–calcium-based binders such as sevelamer (Renagel) are increasing in use, particularly in older children and adolescent patients who are prone to hypercalcemia. Because aluminum may be absorbed from the GI tract and can lead to aluminum toxicity, aluminum-based binders should be avoided.

The cornerstone of therapy for renal osteodystrophy is vitamin D administration. Vitamin D therapy is indicated in patients with 1,25-dihydroxy-vitamin D levels below the established goal range for the child’s particular stage of CKD or in patients with PTH levels above the established goal range for CKD stage. Patients with low 1,25-dihydroxy-vitamin D and elevated PTH levels should be treated with 0.01-0.05 µg/kg/24 hr of calcitriol (Rocaltrol, 0.25-µg capsules or 1 µg/mL suspension). Newer activated vitamin D analogs such as paricalcitol and doxercalciferol are increasingly used, especially in patients who are predisposed to hypercalcemia. Phosphate binders and vitamin D should be adjusted to maintain the PTH level within the designated goal range and the serum calcium and phosphorus levels within the normal range for age. Many nephrologists also attempt to maintain the calcium/phosphorus product (Ca × P0.5) at <55 mg²/dL² in adolescents and <65 mg²/dL² in younger children to minimize the possibility of tissue deposition of calcium phosphorus salts with consequent damage.

**Adynamic Bone Disease**

Adynamic bone disease (low-turnover bone disease) has been recognized in children and adults with CKD. The pathologic finding is osteomalacia and is associated with oversuppression of PTH, perhaps related to the widespread use of calcium-containing phosphate binders and vitamin D analogs.

**Fluid and Electrolyte Management**

Most children with CKD maintain normal sodium and water balance, with the sodium intake derived from an appropriate diet. Infants and children whose CKD is a consequence of renal dysplasia may be polyuric, with significant urinary sodium or free water losses. These children may benefit from high-volume, low-caloric-density feedings with sodium supplementation. Children with high blood pressure, edema, or heart failure may require sodium restriction and diuretic therapy. Fluid restriction is rarely necessary in children with CKD until the development of ESRD requires the initiation of dialysis.

In most children with CKD, potassium balance is maintained until renal function deteriorates to the level at which dialysis is initiated. Hyperkalemia can develop, however, in patients with moderate renal insufficiency who have excessive dietary potassium intake, severe acidosis, or hyporeninemic hypoaldosteronism (related to destruction of the renin-secreting juxtaglomerular apparatus). Hyperkalemia may be treated by restriction of dietary potassium intake, administration of oral alkalinizing agents, and/or treatment with Kayexalate.

**Acidosis**

Metabolic acidosis develops in almost all children with CKD as a result of decreased net acid excretion by the failing kidneys. Either Bicitra
Adjunctive agents in children with CKD whose blood pressure cannot be controlled using dietary sodium restriction, diuretics, and ACE inhibitors.

**Immunizations**

Children with CKD should receive all standard immunizations according to the schedule used for healthy children. An exception must be made in withholding live virus vaccines from children with CKD related to glomerulonephritis, or any disease, during treatment with immunosuppressive medications. It is critical, however, to make every attempt to administer live virus vaccines for measles, mumps, rubella, and varicella before kidney transplantation. These vaccines are not advised for use in immunosuppressed patients. All children with CKD should receive a yearly influenza vaccine. Data from a number of studies suggest that children with CKD might respond suboptimally to immunizations.

**Adjustment in Drug Dose**

Because many drugs are excreted by the kidneys, their dosing might need to be adjusted in patients with CKD to maximize effectiveness and minimize the risk of toxicity. Strategies in dosage adjustment include lengthening of the interval between doses or decreasing the absolute dose, or both. Such adjustments become even more important as pharmacogenomic profiling of drug metabolism becomes routine.

**Progression of Disease**

Although there are no definitive treatments to improve renal function in children or adults with CKD other than treatment of a specific underlying disorder when possible, there are several general strategies that may be effective in slowing the rate of progression of renal dysfunction. Optimal control of hypertension (maintaining the blood pressure at lower than the 75th percentile and perhaps even lower) is critical in all patients with CKD. ACE inhibitors or angiotensin II receptor blockers should be the antihypertensive drugs of choice in hypertensive children with chronic proteinuric renal disease as previously noted. Such agents should also be strongly considered in children with CKD who have significant proteinuria, even in the absence of hypertension, although there are no controlled studies to support this approach. Serum phosphorus should be maintained within the normal range for age and the calcium–phosphorus product $<55$ to minimize renal calcium–phosphorus deposition. Prompt treatment of infectious complications and episodes of dehydration can minimize additional loss of renal parenchyma.

Other potentially beneficial recommendations include correction of anemia with erythropoietin or darbepoetin alfa therapy, control of hyperlipidemia, avoidance of cigarette smoking, prevention of obesity, and avoidance of nonsteroidal antiinflammatory and other potentially nephrotoxic medications. This includes a variety of illegal street drugs as well as herbal and/or homeopathic medications or “supplements.” Although dietary protein restriction may be useful in adults, this recommendation is generally not suggested for children with CKD because of the concern about adverse effects on growth and development.

**Bibliography is available at Expert Consult.**

### 535.3 End-Stage Renal Disease

*Rajasree Sreedharan and Ellis D. Avner*

ESRD represents the state in which a patient's renal dysfunction has progressed to the point at which homeostasis and survival can no longer be sustained with native kidney function and maximal medical management. At this point, renal replacement therapy (dialysis or renal transplantation) becomes necessary. The ultimate goal for children with ESRD is successful kidney transplantation (see Chapter 536).
Renal Failure

Chapter 535

Bibliography

because it provides the most normal lifestyle and possibility for rehabilitation for the child and family.

In the United States, 75% of children with ESRD require a period of dialysis before transplantation can be performed. It is recommended that plans for renal replacement therapy be initiated when a child reaches stage 4 CKD. The optimal time to actually initiate dialysis, however, is based on a combination of the biochemical and clinical characteristics of the patient including refractory fluid overload, electrolyte imbalance, acidosis, growth failure, or uremic symptoms, including fatigue, nausea, and impaired school performance. In general, most nephrologists attempt to initiate dialysis early enough to prevent the development of severe fluid and electrolyte abnormalities, malnutrition, and uremic symptoms. Preemptive transplantation before initiation of dialysis is increasingly being utilized.

The selection of dialysis modality must be individualized to fit the needs of each child. In the United States, two thirds of children with ESRD are treated with peritoneal dialysis, whereas one third are treated with hemodialysis. Age is a defining factor in dialysis modality selection: 88% of infants and children from birth to 5 yr of age are treated with peritoneal dialysis, and 54% of children >12 yr of age are treated with hemodialysis.

**Peritoneal dialysis** is a technique that employs the patient’s peritoneal membrane as a dialyzer. Excess body water is removed by an osmotic gradient created by the high dextrose concentration in the dialysate; wastes are removed by diffusion from the peritoneal capillaries into the dialysate. Access to the peritoneal cavity is achieved by a surgically inserted, tunneled catheter.

Peritoneal dialysis may be provided either as continuous ambulatory peritoneal dialysis or as an automated therapy using a cycler (continuous cyclic peritoneal dialysis, intermittent peritoneal dialysis, or nocturnal intermittent peritoneal dialysis). The majority of U.S. children treated with peritoneal dialysis use cycler-driven therapy, which allows the child and family to be free of dialysis demands during the waking hours. The exchanges are performed automatically during sleep by machine. This permits an uninterrupted day of activities, a reduction in the number of dialysis catheter connections and disconnections (which decreases the risk of peritonitis), and a reduction in the time required by patients and parents to perform dialysis, reducing the risk of fatigue and burnout. Because peritoneal dialysis is not as efficient as hemodialysis, it must be performed daily rather than 3 times weekly. Table 535-8 outlines the benefits of peritoneal dialysis.

**Hemodialysis**, unlike peritoneal dialysis, is usually performed in a hospital setting. Children and adolescents typically have 3 treatments (3-4 hr each) per wk during which fluid and solute wastes are removed. Access to the child's circulation is achieved by a surgically created arteriovenous fistula, graft, or indwelling subclavian or internal jugular catheter.

Bibliography

Kidney transplantation is the optimal therapy for children with end-stage renal disease (ESRD). Five yr survival rates in children who receive a kidney transplant are greater than survival rates of those who remain on hemodialysis or peritoneal dialysis. Children and adolescents with ESRD have special needs that differ from adults, including the need to achieve normal growth and cognitive development. Successful transplantation leads to improvement in their linear growth and allows them to attend school and be free of dietary restrictions. Immunosuppression protocols that employ steroid minimization or avoidance after transplantation demonstrate dramatic improvements in growth patterns for young children after transplantation. Improvements in surgical techniques and a reduction in the early complications of thrombosis have given young children the best long-term outcomes of all age groups among transplant recipients.

**INCIDENCE AND ETIOLOGY**

The incidence of ESRD in pediatric patients in the United States varies by age group (Table 536-1). There is an adjusted incident rate of 14.4 per million population for ages 0-19 yr. The etiology of ESRD in children varies significantly by age (Table 536-2). Congenital, hereditary, and cystic diseases cause ESRD in more than 52% of children 0-4 yr of age, whereas glomerulonephritis and focal segmental glomerulosclerosis (FSGS) account for 38% of cases of ESRD in patients 10-19 yr of age. The most common diagnosis in children with transplanted kidneys is structural disease (49%), followed by various forms of glomerulonephritis (14%) and FSGS (12%).

**INDICATIONS**

Almost all children with ESRD are considered to be candidates for renal transplantation. There are very few absolute contraindications for pediatric kidney transplantation. Relative contraindications include children with preexisting metastatic malignancy or HIV. Patients with remission of malignancy off maintenance treatment for a minimum of 2 yr may be reconsidered on an individual basis for transplantation, with close posttransplantation surveillance. Similarly, patients with autoimmune diseases resulting in ESRD are candidates for transplantation after a period of immunologic quiescence of the primary disease for a period of at least 1 yr before transplantation. Another relative contraindication includes severe neurologic dysfunction, but the wishes of the parents and the potential for rehabilitation must be considered.
Renal transplantation is considered for any child when renal replacement therapy is indicated. In children, dialysis may be required for a period before transplantation to optimize nutritional and metabolic conditions, to achieve an appropriate size in small children, or to keep a patient stable until a suitable donor is available. For young infants, a recipient may need to weigh at least 8-10 kg to minimize the risk for vascular thrombosis and to accommodate an adult-size kidney. This can require a period of dialysis support until the child is at least 12-18 mo of age. Transplantation with an adult-size kidney has been successful in children who weighed <10 kg or were <6 mo of age.

Preemptive transplantation (i.e., transplantation without prior dialysis) continues to account for approximately 25% of all pediatric renal transplants, based mostly on a desire by the child and the family to avoid dialysis. There may be a small benefit in allograft outcome if transplantation occurs without prior dialysis, which might relate to a lower incidence of infections and cardiovascular risk factors. Preemptive renal transplant should be considered when the glomerular filtration rate (GFR) is <10-15 mL/min/1.73 m² and with symptomatic ESRD or rapidly declining GFR and need for dialysis within 6-12 mo. The rates of preemptive transplantation differ moderately for different age groups, being 20% for recipients age ≤2 yr, 24% for age 2-5 yr, 28% for age 6-12 yr, and 22% for age 13-17 yr.

### Characteristics of Donors and Recipients

Almost half of all pediatric kidney transplants come from living donors. The highest rates of transplantation are in the 5-9 yr old group, with 40 live donor transplants and 46 cadaver donor transplants performed per 100 dialysis patient-years. The Organ Procurement and Transplantation Network (OPTN) provides preference for children waiting for a deceased-donor renal transplant. Owing to improved outcomes in deceased-donor pediatric transplantation using donors 5-35 yr of age, OPTN in 2005 implemented a pediatric kidney allocation policy that gave priority for kidneys from deceased donors <35 yr of age. These kidneys were assigned to recipients <18 yr, after 0 mismatch transplants, recipients with a panel reactive antibody >80, or candidates receiving a kidney with a nonrenal origin. This policy shortened the wait time for children versus adults and is associated with improved outcomes.

Living-donor kidney transplantation graft survival has improved over the years, and from 2003-2007 the graft survival rate in living-donor renal transplants was 96.1%, unchanged from the 1999-2002 rate of 95.9%. Graft survival rates for deceased donors from 2003-2007 are 94.4%, also improved from 92.7% in 1999-2002. For children awaiting deceased-donor renal transplants the goals are to minimize waiting times, transplanting kidneys into children 0-6 yr of age within 6 mo, children 7-12 yr within 12 mo, and children 12-18 yr within 18 mo.

### Evaluation and Preparing for Transplantation

The team approach includes evaluations by a transplantation surgeon, nephrologist, nutritionist, social worker, psychologist, financial counselor, pretransplantation nurse, and dialysis nurse (if the patient is undergoing dialysis).

**Primary renal disease can recur** in a number of renal diseases, but it is not a contraindication to transplantation. Recurrent disease in the renal graft accounts for graft loss in almost 7% of primary transplants and 10% in repeat transplantations.

With FSGS and primary oxalosis, patients are at risk for major renal function impairment with recurrence of disease. Grafts in approximately 20-30% of patients with the diagnosis of FSGS fail because the disease recurs. In patients with the original disease of FSGS whose grafts fail, the mean time to failure is 17 mo. Alport syndrome can recur as an anti–glomerular basement membrane (anti-GBM) glomerulonephritis in approximately 3-4% of patients after transplantation and lead to graft loss. Histologic evidence of recurrence of membranoproliferative glomerulonephritis type I occurs widely, from 20% to 70%, and graft loss can occur in ≤50% of cases. Histologic recurrence of membranoproliferative glomerulonephritis type II disease occurs in virtually all cases, with graft loss in ≤50% cases. Histologic recurrence with mesangial immunoglobulin (Ig) A deposits is common and occurs in about half of the patients with IgA nephropathy and in approximately 30% of patients with Henoch-Schönlein purpura. Congenital nephrotic syndrome rarely recurs after transplantation, although patients can develop antinephrin antibodies and present with nephrotic syndrome. Some cases (~25%) of nephrotic syndrome after transplantation are likely de novo. Membranous nephropathy occurs very rarely in children. The recurrence rate after kidney transplantation for patients who have been treated for Wilms tumor is approximately 13%.

Owing to the high risk of developing Wilms tumor, patients with Denys-Drash syndrome should undergo bilateral nephrectomy before transplantation. Other indications for bilateral native nephrectomies include hyposthenuria with polyuria, significant proteinuria, and severe hypertension resistant to medical management. Nephrectomies are also indicated in cases such as polycystic kidney disease, where more room may be needed to place the transplanted kidney and to create space in the abdominal cavity to improve feeding tolerability and the infant’s ability to thrive.

Failure to maintain adequate perfusion of the adult-size kidney, secondary to a “perfusion steal” by the native kidneys results in a histologic picture of “chronic” acute tubular necrosis and a negative impact on graft function.

**Urologic problems**, such as vesicoureteral reflux, posterior urethral valves, abnormal urinary bladders, and/or neurogenic bladders, should be addressed before surgery. Malformations and voiding abnormalities (e.g., neurogenic bladder, bladder dysynergia, remnant posterior urethral valves, and urethral strictures) should be identified and repaired if possible. Children with urologic disease and renal dysplasia often require multiple operations to optimize urinary tract anatomy and function. Such procedures include ureteric reimplantation to correct vesicoureteral reflux, bladder augmentation or reconstruction, creation of a vesicocutaneous fistula by using the appendix to provide a simple, continent, and cosmetically acceptable way for intermittent
catheterization (Mitrofanoff procedure), and excision of duplicated systems or ectopic ureteroceles that could cause recurrent infections. There are reports of excellent outcomes often being achieved in posterior urethral valve bladders by following a staged procedure of initial valve resection to limit any injury to the posterior urethra, and bladder rehabilitation, without the requirement of augmentation, by a process of regimented double voiding.

A comprehensive nutritional assessment needs to be done to ensure that optimal nutritional status is achieved before transplant. Many children with ESRD and especially those on dialysis require nutritional supplements to provide them with sufficient protein and calories. Infants and young children on dialysis often require nasogastic or gastric tube feedings to overcome decreased oral intake from nausea and anorexia due to uremia. Optimal outcomes result from transplanting adult-size kidneys from living donors when the child weighs ≥210 kg.

Bone disease needs to be evaluated for and treated before transplantation. Secondary hyperparathyroidism needs to be treated before transplant to avoid posttransplant urinary phosphate wasting and hypercalcemia. High calcium phosphorus product before transplantation leads to vascular stiffness and calcifications, increasing the patient's risk for cardiovascular disease.

In the United States, >25% of the mortality in children on maintenance dialysis is a result of cardiovascular disease. Cardiac death is the leading cause of death in young patients after transplant in childhood. Therefore, evaluation of cardiac function is required before a kidney transplant in a pediatric patient to be sure that patient has sufficient cardiac function to tolerate the large fluid load that accompanies kidney transplantation. All patients being evaluated for kidney transplant have at least an echocardiogram and electrocardiogram. Hypertension is common and can result from fluid overload and/or intrinsic native renal disease. Blood pressure needs to be under optimal control before transplant. If blood pressure cannot be controlled with medical management, bilateral nephrectomy may need to be performed before transplant to control the hyperreninemic response from the failing kidneys.

Anemia needs to be treated before transplantation. Most patients are taking erythropoietin, folate, and iron to maintain goals for hemoglobin levels between 11 and 12 g/dL. Blood transfusions should be avoided owing to concerns for sensitizing the patient to human leukocyte antigens before transplant. If a blood transfusion is required, patients should receive cytomegalovirus negative, leukoreduced red blood cells. Blood should not be irradiated owing to concerns for trauma to the cells and potential for increased antigen exposure.

Evaluation for venous thrombosis and hypercoagulable states is important before renal transplantation. The third leading cause of graft failure is vascular thrombosis; the leading causes are chronic (34.9%) and acute (13.1%) rejection. Risk factors for graft thrombosis include surgical technique, perfusion and reperfusion injury of graft, young donor age (<2 yr), young recipient (<5 yr), cold ischemia time ≥24 hr, arterial hypotension, prior history of peritoneal dialysis, and/or hypoperfusion of adult kidney transplant in a small child. Particularly in the young recipient, before transplantation, there needs to be evaluation for thrombosis of iliac vessels or inferior vena cava if the patient has had previous surgery or central line placement. Femoral line catheterizations greatly increase the risk for inferior vena cava thrombosis. Children who have large protein losses, such as from nephrotic syndrome and/or peritoneal dialysis, can be at increased risk for thrombosis because of protein loss, such as protein S, protein C, and antithrombin III. Doppler ultrasound, computed tomographic angiography, and magnetic resonance angiography have all been used to evaluate vessels. Magnetic resonance angiography has been used less owing to the concern about exposure to gadolinium and nephrogenic systemic fibrosis. In patients with renal compromise receiving contrast media, intravenous hydration is needed before and after the study for patients with residual renal function, acidosis should be corrected before giving contrast, and N-acetyl cysteine should be administered before and after the CT angiogram to reduce the risk of contrast nephropathy. If the patient is on dialysis, dialysis clearance can be done after contrast administration; hemodialysis is the optimal method for clearance.

Infections need to be identified and treated before transplantation. Infectious disease screening includes a complete history of household contacts with treatment for active or latent tuberculosis, vaccine history for varicella and pertussis, travel history within the past 2 yr and/or if there was significant time spent in another country, history of bacille Calmette-Guérin, animal and/or insect exposure, sexual activity, and consumption of high-risk foods such as unpasteurized products. Screening includes tuberculosis skin test (purified protein derivative), cytomegalovirus IgG, Epstein-Barr virus (EBV) antibody panel, varicella titer, measles antibody, hepatitis B serologies, hepatitis C antibody, HIV, and toxoplasmosis. Additional testing for patients who lived in or visited the central valleys of California, Utah, Nevada, Arizona, and/or New Mexico includes Coccidioides immunodiffusion. Patients from the Ohio River valley should also have Histoplasma antibody checked. Patients from Mexico should have Coccidioides immunodiffusion, Histoplasma antibody, and ova and parasite screen to evaluate for Strongyloides. Those from South America should have Coccidioides immunodiffusion, Histoplasma antibody, and Toxoplasma antibody. Sexually active patients should also be screened for syphilis, gonorrhea, HIV, and Chlamydia.

Immunizations need to be up to date before transplantation. All live vaccines need to be given before transplantation because these vaccines should not be given to immunosuppressed patients. Therefore, measles-mumps-rubella and varicella should be given before transplant and antibody titers should be checked to monitor for response. Measles-mumps-rubella may be given as early as 6 mo of age. Inhaled influenza vaccine should not be given to transplant patients, family members, or healthcare providers.

Psychiatric evaluation should be performed before transplantation to evaluate patients’ and their families’ ability to cope with the stresses that accompany caring for a child with a kidney transplant. A psychologist should also evaluate the patient and their caregivers for depression, substance abuse, and/or noncompliance so that problems can be identified and managed before kidney transplantation. If noncompliance is identified or anticipated, interventions should be in place before transplantation. These should include social and psychiatric interventions, where possible.

Children need ≥2 ABO blood types checked before being listed for a kidney transplantation and a donor should be sought who shares HLA-A, HLA-B, and/or HLA-DR antigens. The 2008 North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) data have shown increased risk for rejection and graft failure with 2-DR mismatch compared to a 0-DR mismatch. The recipient's blood is also checked to see if the patient is sensitized. Patients can become sensitized by prior transplant, blood transfusions, sepsis, and/or pregnancy.

IMMUNOSUPPRESSION
Most pediatric kidney transplant centers employ a combination of drug therapy consisting of a calcineurin inhibitor and corticosteroids with or without an antiproliferative agent. Approximately 80% of transplantation patients receive a 3-drug regimen at 6 mo after transplantation. The rationale for this combination therapy in children is to provide effective immunosuppression and at the same time minimize the toxicity of any single drug.

Induction Therapy
Induction therapy is commonly used in pediatric renal transplant recipients to prevent acute rejection. Graft survival rates are higher in patients treated with antilymphocyte induction therapy. Acute rejection episodes are approximately 30% less frequent and tend to occur later. Induction therapy may consist of T-cell antibodies, interleukin-2 receptor antibodies, and/or therapies that target B cells.

T-Cell Antibodies
Antithymocyte globulin (ATGAM) and Thymoglobulin are polyclonal antibodies that should be given intravenously through a central line to avoid sclerosis and injury to smaller vessels. These medications are
used to prevent the development of the first rejection. Thymoglobulin
is polyclonal antibodies against human T-lymphocyte antigens result-
ing in a rapid depletion of T lymphocytes. Some limit the use of Thy-
moglobulin induction to sensitized high-risk patients or patients who
have concerns for delayed graft function and want to avoid high calci-
nearin inhibitor levels in the early postoperative period. Dosage is
1.5-2.0 mg/kg/dose, with daily monitoring of CD3+ subsets; the dose
should not be given if the CD3+ count exceeds 20 cells/mm³.

OKT3 is a monoclonal antibody that is also given daily for 10-14
days. Studies have not shown a clear advantage using OKT3.

Interleukin-2 Receptor Antibodies
Monoclonal antibodies, such as basiliximab and daclizumab, chimeric
or humanized monoclonal anti-CD25 antibodies, prevent T-cell pro-
iferation but do not cause T-cell depletion. Basiliximab is given on day
0 and day 4 of the transplant as 12 mg/m²/dose in children. Dacli-
zumab is given on day 0 and then every 2 wk for a total of 5 doses at
1 mg/kg/dose in patients with steroid-based immunosuppression.
Patients who are steroid free receive a 2 mg/kg dose on day 0 and the
remaining doses at 1 mg/kg at wk 2, 4, 6, 8, 11, 15, 19, and 23. This
provides the patient with extra immunosuppression for 3 mo for
steroid-based patients and 6 mo for steroid-free patients. Patients tend
to tolerate IL-2 receptor antagonists well. With the withdrawal of dacli-
zumab from the market because of manufacturing deficits, many pedi-
atric transplantation programs are using basiliximab or a short course
(3 days) of Thymoglobulin at 1.5 mg/kg/day for children at low risk of
sensitization and the recommended dosing of Thymoglobulin (5-7
days) or alemtuzumab for children at high risk of sensitization (see
below).

Alemtuzumab (Campath-1H) is a monoclonal antibody against
CD52 antigen present on T and B cells, monocytes, and natural killer
cells. The pediatric data on the use of alemtuzumab show promising
results.

Other Induction Therapies
Other induction therapies for highly sensitized patients include
targeting B cells and/or removing neutralizing antibodies by using
rituximab against the CD20 epitope on early- and intermediate-lineage
B cells, the proteosome inhibitor bortezomib, and plasmapheresis
and/or high-dose intravenous immunoglobulin for removing donor-
specific antibodies.

Belatacept is a fusion protein composed of the Fc fragment of a
human IgG, linked to the extracellular domain of CTLA-4, which is a
molecule crucial for T-cell costimulation, selectively blocking the
process of T-cell activation. Belatacept usage extends from induction
to limited maintenance therapy, and is intended to provide optimal
immunosuppression and limiting of the toxicity generated by standard
immune-suppressing regimens, such as calcineurin inhibitors, thus
limiting fibrosing graft injury and improving renal function. Compli-
cations include a higher incidence and grade of acute rejection epi-
sodes and a higher incidence of posttransplant lymphoproliferative
disorders, with greatest risk in EBV seronegative recipients.

Maintenance Immunosuppression
For maintenance immunosuppression, calcineurin inhibitors, myco-
phenolate mofetil (MMF), steroids, azathioprine, and/or rapamycin
may be used. Most pediatric kidney transplant recipients are main-
tained with a triple-immunosuppressant regimen. Central to many
current pediatric immunosuppressive regimens is a calcineurin inhibi-
tor (cyclosporine or tacrolimus) in combination with steroids and an
adjunctive antiproliferative agent (azathioprine, sirolimus, or MMF).
MMF is used as the adjunctive agent in more than two thirds of the
pediatric kidney transplants performed. Sirolimus is used in 10-15%,
and azathioprine is used in only approximately 2%. Corticosteroids con-
tinue to be used in approximately 80-85% of transplant recipients.

Calcineurin Inhibitors
The side-effect profile of cyclosporine in children is similar to that
seen in adults, but the impact on children is more pronounced.

Hypertrichosis, gingival hyperplasia, and coarsening facial features
may be particularly troublesome in children. Hispanic and African-
American children appear to be at higher risk for significant hypertric-
chosis. In the adolescent population, especially girls, these side effects
can cause severe emotional distress, possibly leading to noncompli-
ance. Seizures, although uncommon, are observed more commonly in
children treated with cyclosporine than in adults. Children are likely
to develop hypercholesterolemia and hypertriglyceridemia and may be
candidates for lipid-lowering agents. Hyperglycemia occurs in <5% of
children treated with cyclosporine.

The hyperlipidemia associated with cyclosporine and other immu-
osuppressive agents is also absent with tacrolimus. On the other
hand, posttransplantation glucose intolerance, tremor, alopecia, and
mild sleep disturbances are more common with tacrolimus. Histori-
cally, posttransplant lymphoproliferative disease has been signifi-
cantly more common in children receiving tacrolimus. The lack of
cosmetic side effects makes tacrolimus a very attractive alternative for
children. This is especially true for young adolescents and female
patients, in whom the cosmetic side effects can lead to noncompliance.

Direct comparative data in pediatrics between cyclosporine and
tacrolimus are limited. The published results comparing these 2 agents
show that overall acute rejection rates at 6 mo were 59.1% versus 36.9% for
cyclosporine and tacrolimus, respectively. In the tacrolimus group,
graft function was better at 1 yr after transplantation. The mean total
steroid dose from time of transplant to 6 mo posttransplantation was
significantly lower in the tacrolimus group. The overall safety profiles
of the 2 calcineurin inhibitors were equivalent, with essentially no dif-
fERENCE in posttransplant lymphoproliferative disorder or in diabetes
requiring insulin treatment. The combination of drugs (tacrolimus and
sirolimus) may be the biggest risk factor for PTLD.

Mycophenolate Mofetil
MMF is the morpholinoethylester prodrug of mycophenolic acid, an
inhibitor of de novo purine synthesis. MMF is part of the initial main-
tenance immunosuppressant regimen in approximately 66% of U.S.
pediatric renal transplant recipients. It has largely replaced azathi-
oprime. Acute rejection rates with MMF are approximately 20-30% when
used with cyclosporine and corticosteroids. When MMF is used with
tacrolimus and/or humanized monoclonal antibodies to the IL-2
receptor, lower rejection rates are usually seen.

The use of MMF has often facilitated the use of a lower dose of
corticosteroids after transplantation. It has also proved useful in calci-
nearin inhibitor–sparing protocols, in which MMF is combined with
sirolimus and corticosteroids. In steroid-avoidance regimens in kidney
transplantation, the bioavailability of mycophenolic acid has been
found to be greater than when the drug is used with steroids. This has
allowed reduced dosing of MMF when combined with steroid avoid-
ance in children. The absence of nephrotoxicity, hyperlipidemia, and
hepatotoxicity has also contributed to the usefulness of MMF.

Gastrointestinal and hematologic side effects can be troublesome.
Most of these instances can be treated with a dosage reduction and/or
brief discontinuation of the drug, with resumption after 7-14 days at a
lower dose. Enteric-coated mycophenolic acid has been shown to
decrease the upper gastrointestinal side effects of MMF in adult trans-
plant recipients.

Sirolimus
Sirolimus, an inhibitor of the mammalian target of rapamycin, is used
primarily as an adjunctive immunosuppressive agent in combination
with a calcineurin inhibitor. It is used in approximately 10-15% of
pediatric renal transplant recipients. Limited anecdotal experience
with sirolimus as a rescue agent in cases of refractory acute rejection,
chronic allograft nephropathy, calcineurin inhibitor nephrotoxicity,
and PTLD has been promising.

Most early reports in pediatric kidney transplantation appear to
describe combinations of sirolimus with either tacrolimus or MMF;
usually these are combined with prednisone, although efficacy has also
been demonstrated with dual therapy (MMF and sirolimus) with com-
plete steroid avoidance.
Corticosteroids
Corticosteroids remain an integral part of many immunosuppressive protocols despite their multifaceted toxicities. In children, retarded skeletal growth is the most noteworthy side effect of corticosteroids. Concerns remain about side effects, such as hypertension, obesity, diabetes mellitus, hyperlipidemia, osteopenia, and aseptic necrosis of bone (particularly the femoral heads). Cosmetic side effects, such as cushingoid faces and acne, are significant additional problems of chronic steroid use. Such side effects often tempt children and adolescent to stop taking their immunosuppressive drugs.

Steroid withdrawal attempts have led to improvements in blood pressure, lipid profiles, and growth. The benefits of steroid withdrawal have been overshadowed by high rates of acute rejection that occur in 25-70% of children. Studies using tacrolimus maintenance have shown safety in late steroid withdrawal, with low rates of acute rejection and no rebound early rejections. A steroid withdrawal trial using sirolimus had low rates of acute rejection but a high incidence of PTLD, which resulted in premature discontinuation of the study.

Complete steroid avoidance has emerged as an alternative strategy to prevent steroid-associated morbidities in children. The immunologic outcomes of these studies are the lower rates of acute rejection seen in these studies compared with standard of care protocols using steroids, suggesting that steroid avoidance might also have immunologic benefits. Building on such observations, investigators at a single center (Stanford University, Stanford, CA) initiated a steroid-avoidance protocol and demonstrated that complete steroid avoidance can be successfully achieved with excellent long-term outcomes at 8 yr, using tacrolimus in combination with MMF, and an extended 6 mo course of daclizumab. Other centers have had similar experience with complete steroid avoidance, using a similar protocol with tacrolimus and MMF and induction with either extended daclizumab or Thymoglobulin. The Stanford steroid-avoidance protocol has been replicated in a randomized multicenter U.S. trial (NIH/NIADD/CTTPT U01 AI-55795) across 12 different pediatric kidney transplant programs in the United States, and this seminal trial confirms the safety of steroid avoidance in low-risk pediatric kidney transplant recipients with lower acute rejection rates, and significant benefits for growth, hypertension, and hyperlipidemia. Importantly, this study also confirmed the overall safety of steroid avoidance, with no adverse effects on generation of donor-specific antibody posttransplantation or histologic injury.

FLUID MANAGEMENT IN INFANTS AND SMALL CHILDREN
Maintenance of adequate blood flow to an adult-sized kidney in an infant or small child is crucial to avoid acute tubular necrosis (ATN) and graft loss from vascular thrombosis and primary nonfunction. The recipient aortic blood flow early after transplantation of an adult-size kidney more than doubles from pretransplantation aortic blood flow. The maximum blood flow that can be obtained in an adult-size kidney transplanted into a small child is approximately 65% of what was in the donor. Low blood flow states such as with hypovolemia or hypotension increase the risk for ATN, graft thrombosis, and graft nonfunction. In the postoperative period, patients are maintained on high fluid volumes.

Close attention is paid to blood pressure and hydration status in the operating room in an attempt to reduce the incidence of delayed graft function. Typically, a central venous catheter is inserted to monitor the central venous pressure throughout the operation. To achieve adequate renal perfusion, a central venous pressure of 12-15 cm H2O should be achieved before removing the vascular clamps; a higher central venous pressure may be desirable in the case of a small infant receiving an adult-size kidney. Dopamine is usually started in the operating room at 2 to 3 μg/kg/min, increased if required, and continued for 24-48 hr postoperatively. It is used to facilitate diuresis and perhaps to affect renal vasodilation. The mean arterial blood pressure is kept ≥65-70 mm Hg by adequate hydration with a crystalloid solution and 5% albumin, and, if necessary, by using dopamine at higher doses. A blood transfusion with packed red blood cells may be required in very small recipients because the hemoglobin can drop as a result of sequestration of approximately 150-250 mL of blood in the transplanted kidney. Mannitol and/or furosemide may be given before removing the vascular clamps to increase the effective circulatory volume and facilitate diuresis. Mannitol can also act as a free-radical scavenger, and together with renal dose dopamine it is a critical factor for minimizing the ischemia–reperfusion injury in steroid-avoidance regimens. After the transplanted kidney starts to produce urine, volume replacement should be immediately started with normal saline.

Infants continue to receive aggressive fluid management by nasogastric or gastrostomy tube feedings of at least 2500 mL/m2/day for 26 mo after transplant if the child is unable to take in sufficient volume. This aggressive fluid management showed 30 mL/min greater GFR in infants who received adult-size kidneys and who were maintained on this higher fluid requirement than infants who were not.

RENAI BIOPSY
Renal biopsy is the gold standard for diagnosis of acute allograft dysfunction. Protocol biopsies may improve graft outcome by detecting early pathology and help monitor drug nephrotoxicity. The largest serial analysis of protocol biopsies at transplantation, 3, 6, 12, and 24 mo posttransplantation (the NIH SNSO1 trial, 2004-9) established that the prime risk factor for chronic histologic injury was discrepancy between recipient size and donor mass and time posttransplantation.

REJECTION
Hyperacute rejection occurs immediately when the kidney is transplanted and is caused by preformed antibodies against the donor HLA, ABO, or other antigens. Hyperacute rejection is rare. The only treatment is removal of the graft.

Acute cellular rejection needs to be identified and treated early. Diagnosis of acute rejection in the very young transplant recipient is often not straightforward. Because most small children receive adult-size kidneys, an elevation in serum creatinine may be a late sign of rejection as a result of the large renal reserve compared with the body mass. Thus, significant allograft dysfunction may be present with little or no increase in the serum creatinine level. One of the earliest and most sensitive signs of rejection is the development of hypertension along with low-grade fever. In children, any increase in serum creatinine, especially if it is accompanied by hypertension, should be considered a symptom of acute rejection until proved otherwise. Late diagnosis and treatment of rejection are associated with a higher incidence of resistant rejections and graft loss. Genomic studies in pediatric kidney transplantation have demonstrated molecular heterogeneity for different acute rejection episodes, not distinguishable by pathologic grading, but with a key established role for B cells as antigen-presenting cells for aggressive T-cell–mediated calcineurin rejection.

Chronic rejection is the leading cause of graft loss and primarily results from immune and nonimmune injuries such as hypertension, diabetes, and hyperlipidemia. Children often have a gradual decline in their renal function and often have fixed proteinuria and hypertension. Despite initial excitement about the potential of MMF and sirolimus mitigating chronic graft injury, this has not translated readily into observable clinical benefits. Humoral immunity, relating the generation of posttransplant donor-specific anti-HLA antibodies, has been implicated in this injury; attention has also shifted to evaluating the impact of non-HLA antibodies after organ transplantation, as direct mediators of organ injury.

GRAFT SURVIVAL
Five yr graft survival is higher in living-donor recipients compared to grafts from deceased donors. The OPTN/SRTR 2007 annual report gives graft survival at 5 yr (2000-2005) for living-donor kidney transplant as 88.0% for recipients 1-5 yr of age, 84.6% for those 6-10 yr of age, and 74.4% for those 11-17 yr of age. Survival in deceased-donor recipients was 74.4% for those 1-5yr of age, 72.1% for those 6-10 yr of age, and 63% for those 11-17 yr of age.

From the NAPRTCS data, graft survival rates of pediatric kidney transplants have improved since 1987 with 1 yr survival rates during 2003-2006 of 95.7% for living-donor transplants and 95%
for deceased-donor transplants. Children <10 yr of age have the best long-term graft and patient survival rates of all transplant recipients. Graft survival in adolescent patients is the lowest of all the age groups. It is well known that noncompliance is a difficult problem in this age group. Other risk factors for graft failure are race, previous transplant history, history of multiple blood transfusions, HLA-B matches, sex, and transplant year. Approximately 25% of pediatric kidney transplants are preemptive. Graft survival for living and deceased-donor kidneys is significantly better in the preemptive group compared to patients who are on dialysis first. The 3 most common causes of graft failure are chronic rejection of graft (34.9%), acute rejection of graft (13%), and vascular thrombosis (10.1%). Approximately 6.4% of patients had graft failure as a result of recurrence of primary disease (NAPRTCS 2007). The NAPRTCS 2003-2007 data showed the probability of the first rejection at 12 mo being 8.7% for the living donor and 17.7% for the deceased donor.

Graft survival is significantly worse in the presence of ATN in either donor group. ATN is defined by NAPRTCS as requiring the use of dialysis within the first transplant week. NAPRTCS 2008 data report a 5.1% delay in graft function in living-donor renal transplants compared to the ATN rate of 16.4% in children who received deceased-donor transplants.

**COMPLICATIONS WITH IMMUNOSUPPRESSION INFECTIONS**

Since the mid-1990s, the incidence of acute rejection has decreased but the incidence of infections after transplantation has been increasing. Pneumonia and urinary tract infection are the most common post-transplant bacterial infections. Urinary tract infections can progress rapidly to urosepsis and may be confused with episodes of acute rejection. Trimethoprim-sulfamethoxazole is used for urinary tract infection antibiotic prophylaxis as well as *Pneumocystis carinii* pneumonia prophylaxis for at least the first 6 mo after transplant. Opportunistic infections associated with unusual organisms usually do not occur until after the first month after transplantation.

The **herpesviruses** (*cytomegalovirus*, *herpesvirus*, *varicella-zoster virus*, and EBV) pose a special problem in view of their common occurrence in children. Many young children have not yet been exposed to these viruses, and because they lack protective immunity, their predisposition to serious primary infection is high. The incidence of *cytomegalovirus* seropositivity is approximately 30% in children <5 yr of age and rises to approximately 60% in teenagers. Thus, the younger child is at a greater potential risk for serious infection when a *cytomegalovirus*-positive donor kidney is transplanted. About half the children are seronegative for EBV, and infection occurs in approximately 75% of these patients. Most EBV infections are clinically silent. PTLD in children may be related to EBV infection in the presence of vigorous immunosuppression. The incidence of these infections is higher in children who receive antibody induction therapy and after treatment of acute rejection. It has also been shown in children that subclinical replication of these viruses is much higher in regimens with maintenance steroids, versus protocols with complete steroid avoidance, and that even subclinical viral replication can have a detrimental effect on the incidence of acute rejection and graft function. Antiviral prophylaxis with ganciclovir and valganciclovir for 3-12 mo after transplantation, especially in the higher-risk groups (recipient-negative, donor-positive), have been effective in reducing the incidence of clinical *cytomegalovirus* disease. Serial surveillance for these viruses by quantitative polymerase chain reaction for viral load in the peripheral blood has also allowed educated minimization of immunosuppression with resultant reduction in viral burden.

![Figure 536-1](https://example.com/fig536.png)  
*Figure 536-1* Surveillance for *cytomegalovirus* and Epstein-Barr virus infections after pediatric kidney transplantation.
Polyomavirus nephropathy is an important cause of allograft dysfunction; almost 30% of children have BK viruria, although allograft dysfunction is observed in lower numbers (~5%). The increased incidence of polyomavirus nephropathy is thought to be the result of more-potent immunosuppressive regimens. A renal biopsy, with identification of polyoma by immunoperoxidase staining, may be required to make the diagnosis with certainty. Reducing immunosuppression is the main form of therapy, and cidofovir and leflunomide are used as adjunctive therapies.

It is important to monitor for PTLD with routine examinations for lymphadenopathy, hepatosplenomegaly, and EBV screen. Figure 536-1 provides a schematic plan to monitor for EBV, cytomegalovirus, and PTLD.

Hypertension, hyperlipidemia, and posttransplant diabetes mellitus are other potential complications of immunosuppressant medications that need to be monitored for and treated when necessary.

Nonadherence with immunosuppressive medications is one of the most important and most elusive problems facing the medical team. At least half of the pediatric deceased-donor transplant recipients demonstrated significant medication nonadherence in the posttransplantation period by using as an assessment direct reporting to the medical team. This figure exceeded 60% in adolescents. Because direct reporting of nonadherence can significantly underestimate its true incidence, this analysis points out the potential magnitude of the problem. Nonadherence appears to be the principal cause of graft loss in 10-15% of all pediatric kidney transplant recipients; for patients with retransplants, this figure might exceed 25%. Risk factors that suggest an increased propensity toward medication nonadherence include female sex, adolescent age, family instability, insufficient emotional support, lower social economic class, and maladaptive behavior.

Although growth improves after transplantation, chronic steroid use does not allow a child to reach full potential height. The precise mechanism by which steroids impair skeletal growth is unknown. Steroids could reduce the release of growth hormone, reduce insulin growth factor activity, impair growth cartilage directly, decrease calcium absorption, or increase renal phosphate wasting. The use of recombinant human growth hormone in pediatric renal transplant recipients significantly improves growth velocity and standard deviation score (SDS). An allograft GFR of <60 mL/min/1.73 m² is associated with poor growth and low insulin growth factor levels; optimal growth occurs with a GFR >90 mL/min/1.73 m². Graft function is the most important factor after a high corticosteroid dosage in the genesis of posttransplantation growth failure. Steroid minimization and withdrawal protocols have demonstrated growth benefits, and the steroid-avoidance data in children show significant catch-up growth at 5 yr after transplantation. These factors have even greater weight than for age-matched, and gender-matched peers. It is thus likely that with a well-functioning kidney and no maintenance steroids, children might now be able to realize their full height potential.

LONG-TERM OUTCOME

With advances in transplant care and treatment modalities and with diligent attention to the pediatric patient’s psychosocial, educational, vocational, and developmental rehabilitation, the social and emotional functioning of the child and the child’s family appears to return to preillness levels within 1 yr of successful transplantation. Renal transplantation leads to improvement in linear growth in children. School function tests improve after renal transplantation. Most patients can reenter school and social activities after a short recovery time of 4-6 wk after surgery. A 3 yr follow-up shows that nearly 90% of children are in their appropriate school or job placement positions. Surveys of 10 year survivors of pediatric kidney transplants report that most patients consider their health to be good, and they engage in appropriate social, educational, and sexual activities while experiencing a very good to excellent quality of life.

Chapter 537
Congenital Anomalies and Dysgenesis of the Kidneys
Jack S. Elder

EMBRYONIC DEVELOPMENT
The kidney is derived from interaction between the ureteral bud and the metanephric blastema. During the 5th wk of gestation, the ureteral bud arises from the mesonephric (wolffian) duct and penetrates the metanephric blastema, which is an area of undifferentiated mesenchyme on the nephrogenic ridge. The ureteral bud undergoes a series of approximately 15 generations of divisions and by the 20th wk of gestation forms the entire collecting system: the ureter, renal pelvis, calyces, papillary ducts, and collecting tubules. Signals from the mesenchymal cells induce ureteric bud formation from the wolffian duct as well as ureteric bud branching. Reciprocal signals from the ureteric bud and, later, from its branching tips induce mesenchymal cells to condense, proliferate, and convert into epithelial cells. Under the inductive influence of the ureteral bud, nephron differentiation begins during the 7th wk of gestation. By the 20th wk of gestation, when the collecting system is developed, approximately 30% of the nephrons are present. Nephrogenesis continues at a nearly exponential rate and is complete by the 36th wk of gestation. During nephrogenesis, the kidneys ascend to a lumbar site just below the adrenal glands. At least 16 signaling agents have been identified that regulate renal development.

The fetal kidneys play a minor role in the maintenance of fetal salt and water homeostasis. The rate of urine production increases throughout gestation; at term, volumes have been reported to be 50 mL/hr. The glomerular filtration rate is 25 mL/min/1.73 m² at term and triples by 3 mo postterm. The increase in glomerular filtration rate is caused by a reduction in intrarenal vascular resistance and redistribution of intrarenal blood flow to the cortex, where more nephrons are located.

RENAL AGENESIS
Renal agenesis, or absent kidney development, can occur secondary to a defect of the wolffian duct, ureteric bud, or metanephric blastema. Unilateral renal agenesis has an incidence of 1 in 450-1,000 births. Unilateral renal agenesis often is discovered during the course of an evaluation for other congenital anomalies (VACTERL [vertebral defects, imperforate anus, congenital heart disease, tracheoesophageal fistula, renal and limb defects] syndrome; e.g., see Chapter 344). Its incidence is increased in newborns with a single umbilical artery. In true agenesis, the ureter and the ipsilateral bladder hemitrigone are absent. The contralateral kidney undergoes compensatory hypertrophy, to some degree prenatally but primarily after birth. Approximately 15% of these children have contralateral vesicoureteral reflux, and most males have an ipsilateral absent vas deferens because the wolffian duct is absent. Because the wolffian and müllerian ducts are contiguous, müllerian abnormalities in girls also are common. The Mayer-Rokitansky-Küster-Hauser syndrome (1 in 4,000-1 in 10,000 female births) is a group of associated findings that may include vaginal aplasia, uterine maldevelopment, and normal ovaries. Two types are described—type I and type II. In type II, renal anomalies, for example, unilateral renal agenesis or a horseshoe kidney, are common, and skeletal anomalies are present in 10% (see Chapter 554).

Renal agenesis is distinguished from aplasia, in which a nubbin of nonfunctioning tissue is seen capping a normal or abnormal ureter. This distinction may be difficult but usually is clinically insignificant. Unilateral renal agenesis is diagnosed in some patients based on the finding of an absent kidney on ultrasonography or renal scintigraphy (renal scan). Some of these patients were born with a hypoplastic kidney or a multicystic dysplastic kidney that underwent complete cyst regression. Although the specific diagnosis is not critical, if the finding of an absent kidney is based on an ultrasonogram, a functional imaging study such as an MR urogram or renal scan should be performed because some of these patients have an ectopic kidney in the pelvis. If there is a normal contralateral kidney, long-term renal function usually remains normal.

Bilateral renal agenesis is incompatible with extrauterine life and produces the Potter syndrome. Death occurs shortly after birth from pulmonary hypoplasia. The newborn has a characteristic facial appearance, termed Potter facies (Fig. 537-1). The eyes are widely separated with epicanthic folds, the ears are low set, the nose is broad and compressed flat, the chin is receding, and there are limb anomalies. Bilateral renal agenesis should be suspected when maternal ultrasonography demonstrates oligohydramnios, nonvisualization of the bladder, and absent kidneys. The incidence of this disorder is 1 in 3,000 births, with a male predominance, and represents 20% of newborns with the Potter phenotype. Other common causes of neonatal renal failure associated with the Potter phenotype include cystic renal dysplasia and obstructive uropathy. Less-common causes are autosomal recessive polycystic kidney disease (infantile), renal hypoplasia, and medullary dysplasia. Neonates with bilateral renal agenesis die of pulmonary insufficiency from pulmonary hypoplasia rather than renal failure (see Chapter 101).

The term familial renal dysplasia describes families in which renal agenesis, renal dysplasia, multicystic kidney (dysplasia), or a combination, occurs in a single family. This disorder has an autosomal dominant inheritance pattern with a penetrance of 50-90% and variable expression. Because of this association, some clinicians advise screening 1st-degree relatives of persons who have renal agenesis or dysplasia, but this is not standard practice.

Whether persons with a solitary kidney should avoid contact sports such as football and karate is unresolved. The arguments favoring participation are that there are other solitary organs (spleen, liver, and brain) that do not preclude participation in contact sports, and there have been only a few reports of persons losing a kidney from sports injuries. The arguments against such participation are that the contralateral normal kidney is hypertrophied and not as well protected by the ribs, and a serious renal injury could have serious lifelong consequences. The American Academy of Pediatrics recommends an “individual assessment for contact, collision, and limited-contact sports.”

RENAL DYSGENESIS: DYSPLASIA, HYPOPLASIA, AND CYSTIC ANOMALIES
Renal dysgenesis refers to maldevelopment of the kidney that affects its size, shape, or structure. The 3 principal types of dysgenesis are dysplastic, hypoplastic, and cystic. Although dysplasia always is accompanied by a decreased number of nephrons (hypoplasia), the converse is not true: Hypoplasia can occur in isolation. When both conditions are
present, the term hypodysplasia is preferred. The term dysplasia is technically a histologic diagnosis and refers to focal, diffuse, or segmentally arranged primitive structures, specifically primitive ductal structures, resulting from abnormal metanephric differentiation. Nonrenal elements, such as cartilage, also may be present. The condition can affect all or only part of the kidney. If cysts are present, the condition is termed cystic dysplasia. If the entire kidney is dysplastic with a preponderance of cysts, the kidney is referred to as a multicystic dysplastic kidney (MCDK) (Fig. 537-2).

The pathogenesis of dysplasia is multifactorial. The “bud” theory proposes that if the ureteral bud arises in an abnormal location, such as an ectopic ureter, there is abnormal penetration and induction of the metanephric blastema, which causes abnormal kidney differentiation, resulting in dysplasia. Renal dysplasia also can occur with severe obstructive uropathy early in gestation, as with the most severe cases of posterior urethral valves or in an MCDK, in which a portion of the ureter is absent or atretic.

MCDK is a congenital condition in which the kidney is replaced by cysts and does not function; it can result from ureteral atresia. Kidney size is highly variable. The incidence is approximately 1 in 2,000. Some clinicians incorrectly use the terms multicystic kidney and polycystic kidney interchangeably. However, polycystic kidney disease is an inherited disorder that may be autosomal recessive or autosomal dominant and affects both kidneys (see Chapter 521). MCDK usually is unilateral and generally is not inherited. Bilateral MCDKs are incompatible with life.

MCDK is the most common cause of an abdominal mass in the newborn, but the vast majority are nonpalpable at birth. In most cases, it is discovered incidentally during prenatal sonography. In some patients, the cysts are identified prenatally, but the cysts regress in utero and no kidney is identified on imaging at birth. Contralateral hydronephrosis is present in 5-10% of patients. Sonography shows the characteristic appearance of a kidney replaced by multiple cysts of varying sizes that do not communicate, and no identifiable parenchyma is present. In the past, most cases were confirmed with a renal scan, which should demonstrate nonfunction. However, presently the diagnosis of MCDK is usually straightforward based on the renal ultrasound, and a scan generally is unnecessary. In some patients, usually boys, a small nonobstructing ureterocele is present in the bladder (see Chapter 540). Although 15% have contralateral vesicoureteral reflux, it is usually low grade, and obtaining a voiding cystourethrogram also is unnecessary, unless there is significant contralateral hydronephrosis or the child develops an upper urinary tract infection. Management is controversial. Complete cyst regression occurs in nearly half of MCDKs by age 7 yr. The risk of associated hypertension is 0.2-1.2%, and the risk of Wilms tumor arising from an MCDK is approximately 1 in 1,200. Because neoplasms arise from the stromal rather than the cystic component, even if the cysts regress completely, the likelihood that the kidney could develop a neoplasm is not altered.

Because of the occult nature of these potential problems, many clinicians advise annual follow-up with sonography and blood pressure measurement. The most important aspect of follow-up is being certain that the solitary kidney is functioning normally. If there is an abdominal mass, the cysts enlarge, the stromal core increases in size, or hypertension develops, nephrectomy is recommended. In lieu of follow-up screening, laparoscopic nephrectomy may be performed.

Renal hypoplasia refers to a small nondysplastic kidney that has fewer than the normal number of calyces and nephrons. The term encompasses a group of conditions with an abnormally small kidney and should be distinguished from aplasia, in which the kidney is rudimentary. If the condition is unilateral, the diagnosis usually is made incidentally during evaluation for another urinary tract problem or hypertension. Bilateral hypoplasia usually manifests with signs and symptoms of chronic renal failure and is a leading cause of end-stage renal disease during the 1st decade of life. A history of polyuria and polydipsia is common. Urinalysis results may be normal. In a rare form of bilateral hypoplasia called oligomeganephronia, the number of nephrons is markedly reduced and those present are markedly hypertrophied.

The Ask-Upmark kidney, also termed segmental hypoplasia, refers to small kidneys, usually weighing not more than 35 g, with 1 or more
ASSOCIATED PHYSICAL FINDINGS

Upper urinary tract anomalies are more common in children with certain physical findings. The incidence of renal anomalies is increased if there is a single umbilical artery and an abnormality of another organ system (congenital heart disease). External ear anomalies (particularly if the child has multiple congenital anomalies), imperforate anus, and scoliosis are associated with renal anomalies. Infants with these physical findings should undergo a renal sonogram.

Bibliography
PREVALENCE AND ETIOLOGY

Urinary tract infections (UTIs) occur in 1% of boys and 1-3% of girls. The prevalence of UTIs varies with age. During the 1st yr of life, the male:female ratio is 2.8-5.4:1. Beyond 1-2 yr, there is a female preponderance, with a male:female ratio of 1:10. In boys, most UTIs occur during the 1st yr of life; UTIs are much more common in uncircumcised boys, especially in the 1st yr of life. In girls, the first UTI usually occurs by the age of 5 yr, with peaks during infancy and toilet training.

UTIs are caused primarily by colonic bacteria. In girls, 75-90% of all infections are caused by *Escherichia coli* (see Chapter 200), followed by *Klebsiella* spp. and *Proteus* spp. (see Chapter 109). Although *E. coli* is also the most common organism in males, some series report that in boys older than 1 yr of age, *Proteus* is as common a cause as *E. coli*; others report a preponderance of Gram-positive organisms in boys. *Staphylococcus saprophyticus* and enterococcus are pathogens in both
UTIs have been considered a risk factor for the development of renal insufficiency or end-stage renal disease in children, although some have questioned the importance of UTI as an isolated risk factor, because only 2% of children with renal insufficiency report a history of UTI. This paradox may be secondary to better recognition of the risks of UTI and prompt diagnosis and therapy. Furthermore, many children receive antibiotics for fever without a specific diagnosis (e.g., treating a questionable otitis media) resulting in a partially treated UTI.

**CLINICAL MANIFESTATIONS AND CLASSIFICATION**

The 3 basic forms of UTI are pyelonephritis, cystitis, and asymptomatic bacteriuria. Focal pyelonephritis ("nephronia") and renal abscesses are less common.

**Clinical Pyelonephritis**

Clinical pyelonephritis is characterized by any or all of the following: abdominal, back, or flank pain; fever; malaise; nausea; vomiting; and, occasionally, diarrhea. Fever may be the only manifestation. Newborns can show nonspecific symptoms such as poor feeding, irritability, jaundice, and weight loss. Pyelonephritis is the most common serious bacterial infection in infants younger than 24 mo of age who have fever without an obvious focus (see Chapter 177). These symptoms are an indication that there is bacterial involvement of the upper urinary tract. Involvement of the renal parenchyma is termed acute pyelonephritis, whereas if there is no parenchymal involvement, the condition may be termed pyelitis. Acute pyelonephritis can result in renal injury, termed pyelonephritic scarring.

Acute lobar nephronia (acute lobar nephritis) is a renal mass caused by acute focal infection without liquefaction. It may be an early stage in the development of a renal abscess. Manifestations are identical to pyelonephritis; renal imaging demonstrates the abnormality (Fig. 538-1). Renal abscess can occur following a pyelonephritic infection caused by the usual uropathogens or may be secondary to hematogenous infection (Staphylococcus aureus). Perinephric abscess (Fig. 538-2) can occur secondary to contiguous infection in the perirenal area (e.g., vertebral osteomyelitis, psoas abscess) or pyelonephritis that dissects to the renal capsule.

Xanthogranulomatous pyelonephritis is a rare type of renal infection characterized by granulomatous inflammation with giant cells and foamy histiocytes. It can manifest clinically as a renal mass or an acute or chronic infection. Renal calculi, obstruction, and infection with Proteus spp. or E. coli contribute to the development of this lesion, which usually requires total or partial nephrectomy.

**Cystitis**

Cystitis indicates that there is bladder involvement; symptoms include dysuria, urgency, frequency, suprapubic pain, incontinence, and mal-odorous urine. Cystitis does not cause fever and does not result in renal injury. Malodorous urine is not specific for a UTI.

Acute hemorrhagic cystitis often is caused by E. coli; it also has been attributed to adenovirus types 11 and 21. Adenovirus cystitis is more common in boys; it is self-limiting, with hematuria lasting approximately 4 days.

Eosinophilic cystitis is a rare form of cystitis of obscure origin that occasionally is found in children. The usual symptoms are those of...
cystitis with hematuria. On imaging, typically there are multiple solid bladder masses that consist histologically of inflammatory infiltrates with eosinophils. Ureteral dilation with hydroureter also is common. Children with eosinophilic cystitis may have been exposed to an allergen. Bladder biopsy often is necessary to exclude a neoplastic process. Treatment usually includes antihistamines and nonsteroidal antiinflammatory agents.

**Intestinal cystitis** is characterized by irritative voiding symptoms such as urgency, frequency, and dysuria, and bladder and pelvic pain relieved by voiding with a negative urine culture. The disorder is most likely to affect adolescent girls and is idiopathic. Diagnosis is made by cystoscopic observation of mucosal ulcers with bladder distention. Treatments have included bladder hydrodistention and laser ablation of ulcerated areas, but no treatment provides sustained relief.

### Asymptomatic Bacteriuria

**Asymptomatic bacteriuria** refers to a condition in which there is a positive urine culture without any manifestations of infection. It is most common in girls. The incidence is <1% in preschool and school-age girls and is rare in boys. This condition is benign and does not cause renal injury, except in pregnant women, in whom asymptomatic bacteriuria, if left untreated, can result in a symptomatic UTI. Some girls are mistakenly identified as having asymptomatic bacteriuria, whereas they actually are experiencing day or night incontinence or perineal discomfort secondary to UTI; these patients should undergo antibiotic therapy.

### PATHOGENESIS AND PATHOLOGY

Nearly all UTIs are ascending infections. The bacteria arise from the fecal flora, colonize the perineum, and enter the bladder via the urethra. In uncircumcised boys, the bacterial pathogens arise from the flora beneath the prepuce. In some cases, the bacteria causing cystitis ascend to the kidney to cause pyelonephritis. Rarely, renal infection occurs by hematogenous spread, as in endocarditis or in some neonates.

If bacteria ascend from the bladder to the kidney, acute pyelonephritis can occur. Normally the simple and compound papillae in the kidney have an antireflux mechanism that prevents urine in the renal pelvis from entering the collecting tubules. However, some compound papillae, typically in the upper and lower poles of the kidney, allow intrarenal reflux. Infected urine then stimulates an immunologic and inflammatory response. The result can cause renal injury and scarring (Figs. 538-3 and 538-4). Children of any age with a febrile UTI can have acute pyelonephritis and subsequent renal scarring, but the risk is highest in those younger than 2 yr of age.

Table 538-1 lists the host risk factors for UTI. Vesicoureteral reflux is discussed in Chapter 539. If there is grade III, IV, or V vesicoureteral reflux and a febrile UTI, 90% have evidence of acute pyelonephritis on renal scintigraphy or other imaging studies. In girls, UTIs often occur at the onset of toilet training because of bladder/bowel dysfunction that occurs at that age. The child is trying to retain urine to stay dry, yet the bladder may have uninhibited contractions forcing urine out. The result may be high-pressure, turbulent urine flow or incomplete bladder emptying, both of which increase the likelihood of bacteriuria. Bladder/bowel dysfunction can occur in the toilet-trained child who voids infrequently. Similar problems can arise in school-age children who refuse to use the school bathroom. Obstructive uropathy resulting in hydroureter increases the risk of UTI because of urinary stasis. Urethral catheterization for urine output monitoring or during a voiding cystourethrogram or nonsterile catheterization can infect the bladder with a pathogen. Constipation with fecal impaction can increase the risk of UTI because it can cause bladder dysfunction.

The pathogenesis of UTI is based in part on the presence of bacterial pili or fimbriae on the bacterial surface. There are 2 types of fimbriae, type I and type II. Type I fimbriae are found on most strains of *E. coli*. Because attachment to target cells can be blocked by D-mannose, these fimbriae are referred to as mannose sensitive. They have no role in pyelonephritis. The attachment of type II fimbriae is not inhibited by mannose, and these are known as mannose resistant. These fimbriae are known as *mannose resistant*. These fimbriae

---

**Table 538-1  Risk Factors for Urinary Tract Infection**

| Female gender | Tight clothing (underwear) |
| Uncircumcised male | Pinworm infestation |
| Vesicoureteral reflux* | Constipation |
| Toilet training | Bacteria with P fimbriae |
| Voiding dysfunction | Anatomic abnormality (labial adhesion) |
| Obstructive uropathy | Neurogenic bladder |
| Urethral instrumentation | Sexual activity |
| Wiping from back to front in girls | Pregnancy |

*Risk increased for clinical pyelonephritis, not cystitis.
are expressed by only certain strains of *E. coli*. The receptor for type II fimbriae is a glycosphingolipid that is present on both the uroepithelial cell membrane and red blood cells. The Gal 1-4 Gal oligosaccharide fraction is the specific receptor. Because these fimbriae can agglutinate by P blood group erythrocytes, they are known as P fimbriae. Bacteria with P fimbriae are more likely to cause pyelonephritis. Between 76% and 94% of pyelonephritogenic strains of *E. coli* have P fimbriae, compared with 19-23% of cystitis strains.

Other host factors for UTI include anatomic abnormalities precluding normal micturition, such as a labial adhesion. This lesion acts as a barrier and causes vaginal voiding. A neuropathic bladder can predispose to UTIs if there is incomplete bladder emptying and/or detrusor–sphincter dyssynergia. Sexual activity is associated with UTIs in girls, in part because of incomplete bladder emptying. From 4-7% of pregnant women have asymptomatic bacteriuria, which can develop into a symptomatic UTI. The incidence of UTI in infants who are breastfed is lower than in those fed with formula.

**DIAGNOSIS**

UTI may be suspected based on symptoms or findings on urinalysis, or both; a *urine culture is necessary for confirmation and appropriate therapy*. There are several ways to obtain a urine sample; some are more accurate than others. In toilet-trained children, a midstream urine sample usually is satisfactory; the introitus should be cleaned before obtaining the specimen. In uncircumcised boys, the prepuce must be retracted; if the prepuce is not retractable, a voided sample may be unreliable and contaminated with skin flora. According to the 2011 American Academy of Pediatrics (AAP) Clinical Guideline for children 2-24 mo, in children who are not toilet trained, a catheterized or suprapubic aspirate urine sample should be obtained. Alternatively, the application of an adhesive, sealed, sterile collection bag after disinfection of the skin of the genitals can be useful only if the culture is negative or if a single uropathogen is identified. However, a positive culture can result from skin contamination, particularly in girls and uncircumcised boys. If treatment is planned immediately after obtaining the urine culture, a bagged specimen should not be the method because of a high rate of contamination, often with mixed organisms. A suprapubic aspirate generally is unnecessary.

Nitrites and leukocyte esterase usually are positive in infected urine. Microscopic hematuria is common in acute cystitis, but microhematuria alone does not suggest UTI. White blood cell casts in the urinary sediment suggest renal involvement, but in practice these are rarely seen. If the child is asymptomatic and the urinalysis result is normal, it is unlikely that there is a UTI. However, if the child is symptomatic, a UTI is possible, even if the urinalysis result is negative (Table 538-2).

**Pyuria** (leukocytes on urine microscopy) suggests infection, but infection can occur in the absence of pyuria; this finding is more confirmatory than diagnostic. Conversely, pyuria can be present without UTI. Figure 538-3 shows the predictive value of leukocyte esterase, nitrites, and leukocytes.

**Sterile pyuria** (positive leukocytes, negative culture) may occur in partially treated bacterial UTIs, viral infections, renal tuberculosis, renal abscess, UTI in the presence of urinary obstruction, urethritis as a consequence of a sexually transmitted infection (see Chapter 120), inflammation near the ureter or bladder (appendicitis, Crohn disease), or interstitial nephritis (eosinophilic). Prompt plating of the urine sample for culture is important, because if the urine sits at room temperature for more than 60 min, overgrowth of a minor contaminant can suggest a UTI when the urine might not be infected. Refrigeration is a reliable method of storing the urine until it can be cultured.

If the culture shows >50,000 colonies of a single pathogen (suprapubic or catheter sample), or if there are 10,000 colonies and the child is symptomatic, the child is considered to have a UTI. In a bag sample, if the urinalysis result is positive, the patient is symtomatic, and there is a single organism cultured with a colony count >100,000, there is a presumed UTI. If any of these criteria are not met, confirmation of infection with a catheterized sample is recommended.

With acute renal infection, leukocytosis, neutrophilia, and elevated serum erythrocyte sedimentation rate, procalcitonin, and C-reactive protein are common. However these are all nonspecific markers of inflammation, and their elevation does not prove that the child has acute pyelonephritis. With a renal abscess, the white blood cell count is markedly elevated to >20,000-25,000/mm³. An elevated serum procalcitonin level is associated with pyelonephritis and a high risk of renal scarring. Because sepsis is common in pyelonephritis, particularly in infants and in any child with obstructive uropathy, blood cultures should be drawn before starting antibiotics if possible.

According to the 2011 AAP Guidelines for children 2-24 mo, risk factors for girls include white race, age younger than 12 mo, temperature >39°C (102.2°F), fever for longer than 2 days, and absence of another source of infection. Risk factors for boys include nonblack race, temperature >39°C (102.2°F), fever for longer than 24 hr, and absence of another source of infection. Atypical features include failure to respond within 48 hr of appropriate antibiotics, poor urine flow, and an elevated creatinine level.

**TREATMENT**

**Acute cystitis** should be treated promptly to prevent possible progression to pyelonephritis. If the symptoms are severe, presumptive treatment is started pending results of the culture. If the symptoms are mild or the diagnosis is doubtful, treatment can be delayed until the results of culture are known, and the culture can be repeated if the results are uncertain. If treatment is initiated before the results of a culture and sensitivities are available, a 3- to 5-day course of therapy with trimethoprim-sulfamethoxazole (TMP-SMX) or trimethoprim is effective against many strains of *E. coli*. Nitrofurantoin (5-7 mg/kg/24 hr in 3-4 divided doses) also is effective and has the advantage of being active against *Klebsiella* and *Enterobacter* organisms. Amoxicillin (50 mg/kg/24 hr) also is effective as initial treatment but has a high rate of bacterial resistance.

In acute febrile infections suggesting **clinical pyelonephritis**, a 7-14 day course of broad-spectrum antibiotics capable of reaching significant tissue levels is preferable. Children who are dehydrated, are vomiting, are unable to drink fluids, are 1 mo of age or younger, have complicated infection, or in whom urosepsis is a possibility should be admitted to the hospital for IV rehydration and IV antibiotic therapy. Parenteral treatment with ceftriaxone (50-75 mg/kg/24 hr, not to

IMAGING STUDIES IN CHILDREN WITH A FEBRILE UTI

The goal of imaging studies in children with a UTI is to identify anatomic abnormalities that predispose to infection, determine whether there is active renal involvement, and to assess whether renal function is normal or at risk.

There are 2 historical approaches to imaging, the traditional “bottom-up” and the “top-down” approaches.

1. The “bottom-up” method was a renal sonogram plus voiding cystourethrogram; this approach will identify upper and lower urinary tract abnormalities, including vesicoureteral reflux, bladder–bowel dysfunction, and bladder abnormalities, such as a paraureteral diverticulum. It is unlikely to detect renal scarring unless it is significant (renal cortical irregularity, small kidney on renal ultrasound). A dimercaptosuccinic acid (DMSA) scan is necessary to provide the best assessment of renal scarring.

2. The “top-down” approach was intended to reduce the number of VCGU examinations. It begins with a DMSA renal scan, to identify areas of acute pyelonephritic involvement, termed acute pyelonephritis (Fig. 538-5). The DMSA scan in younger children generally requires sedation. This condition is characterized by fever, malaise, abdominal or flank pain, and occasionally nausea and vomiting, and is a significant risk factor for renal injury and scarring. On DMSA, involved areas of the kidney are photopenic and the kidney is enlarged. Of children with a febrile UTI, approximately 50% have a positive DMSA scan. Of those with a positive scan, approximately 50% develop renal scarring in the areas of acute pyelonephritis, and in the remainder with acutely positive scans, the renal appearance will normalize. In children with diluting grades of reflux (III, IV, V), 80-90% with a febrile UTI have a DMSA scan consistent with acute pyelonephritis. Children with grades I and II reflux and those without reflux can also develop acute pyelonephritis. In longitudinal studies of children with grades I and II reflux and acute pyelonephritis, the reflux usually resolves. If the DMSA scan is normal during a febrile UTI, no scarring will result from that particular infection. CT is another diagnostic tool that can image acute pyelonephritis, but clinical experience with DMSA is much greater, and CT scans have significant radiation. If the DMSA scan is positive, then a VCU 5 is performed (Fig. 538-6), because 90% of children with diluting reflux have a positive DMSA scan. If reflux is identified, treatment is based on the perceived long-term risk of the reflux to the child (see Chapter 539). One limitation to this approach is that many hospitals caring for children with a febrile UTI might not have facilities for performing a DMSA scan in children. In these cases, a renal sonogram should be performed, after which the clinician decides whether to send the child to a facility with

---

DMSA capability or instead do a VCUG. In addition, if the DMSA scan is positive, then a follow-up scan is indicated 4-6 mo later to determine whether renal scarring occurred.

The AAP recommends that in a typical first-episode of UTI, initial imaging should be ultrasonography of the kidneys, ureters, and bladder. VCUG is indicated if the ultrasound study is abnormal, the patient has atypical features, or after a recurrent febrile UTI (Table 538-3).

In children with a history of cystitis, (dysuria, urgency, frequency, suprapubic pain), imaging is usually unnecessary. Instead, assessment and treatment of bladder and bowel dysfunction is important. If there are numerous lower UTIs, then a renal sonogram is appropriate, but a VCUG rarely adds useful information.

The AAP recommendation has resulted in a significant decrease in the number of VCUGs ordered. However, the pediatric urologic community has raised numerous concerns regarding the recommendations, and prospective studies will be necessary before determining whether they should be adopted. One consequence is that many primary care physicians have generalized these recommendations, which were intended for children 2-24 mo, to all children.

Similarly, in 2007, the NICE (National Institute for Health and Clinical Excellence, UK) guidelines for diagnosis, management, and imaging after UTI were released (Table 538-4). These recommendations divided children into those younger than 6 mo, 6 mo-3 yr, and older than 3 yr of age. An initial VCUG is recommended only in children younger than age 6 mo. These recommendations are highly controversial.

because the methodology was not based on evidence but on expert opinion. In addition, there was no retrospective or prospective assessment of the potential of this approach to identify significant uropathology. There is evidence that a significant number of children with uropathology would not have been identified under these guidelines.

**PROPHYLAXIS OF RECURRENT URINARY TRACT INFECTION**

See Chapter 539.

In children with a first episode of pyelonephritis in an otherwise anatomically normal urinary tract and no evidence of reflux, no antimicrobial prophylaxis is required in an attempt to prevent a recurrence or renal scarring.

*Bibliography is available at Expert Consult.*
Bibliography

Vesicoureteral reflux (VUR) describes the retrograde flow of urine from the bladder to the ureter and kidney. The ureteral attachment to the bladder normally is oblique, between the bladder mucosa and detrusor muscle, creating a flap-valve mechanism that prevents VUR (Fig. 539-1). VUR occurs when the submucosal tunnel between the mucosa and detrusor muscle is short or absent. Affecting 1-2% of children, VUR usually is congenital and often is familial. VUR is present in approximately 30% of females who had a urinary tract infection and in 5-15% of infants with antenatal hydronephrosis.

VUR predisposes to kidney infection (pyelonephritis) by facilitating the transport of bacteria from the bladder to the upper urinary tract (see Chapter 538). The inflammatory reaction caused by pyelonephritis can result in renal injury or scarring, also termed reflux-related renal injury or reflux nephropathy. In children with a febrile urinary tract infection (UTI), those with VUR are 3 times more likely to develop renal injury compared to those without VUR. Extensive renal scarring impairs renal function and can result in renin-mediated hypertension (see Chapter 445), renal insufficiency or end-stage renal disease (see Chapter 535), impaired somatic growth, and morbidity during pregnancy. Scarring associated with reflux may be present at birth or develop in the absence of infection.

In the past, reflux nephropathy accounted for as much as 15-20% of end-stage renal disease in children and young adults. With greater attention to the management of UTIs and a better understanding of VUR, end-stage renal disease secondary to reflux nephropathy is uncommon. Reflux nephropathy remains a common cause of hypertension in children. VUR in the absence of infection or elevated bladder pressure (e.g., neuropathic bladder, posterior urethral valves) rarely causes renal injury.

**CLASSIFICATION**

VUR severity is graded using the International Reflux Study Classification of I-V and is based on the appearance of the urinary tract on a contrast voiding cystourethrogram (VCUG) (Figs. 539-2 and 539-3). The higher the VUR grade the greater the likelihood of renal injury. VUR severity is an indirect indication of the degree of abnormality of the ureterovesical junction.

VUR may be primary or secondary (Table 539-1). Bladder–bowel dysfunction can worsen preexisting VUR if there is a marginally competent ureterovesical junction. In the most severe cases, there is such massive VUR into the upper tracts that the bladder becomes

---

Grade III: VUR into dilated ureter and/or blunting of calyceal fornices. Grade IV: VUR into a grossly dilated ureter. Grade V: massive VUR, with significant ureteral dilation and tortuosity and loss of the papillary impression.

*Figure 539-3* Voiding cystourethrogram showing grade IV right vesicoureteral reflux.
overdistended. This condition, the megacystis-megaureter syndrome, occurs primarily in boys and may be unilateral or bilateral (Fig. 539-4). Reimplantation of the ureters into the bladder to correct VUR corrects the condition.

Approximately 1 in 125 children have a duplication of the upper urinary tract, in which 2 ureters rather than 1 drain the kidney. Duplication may be partial or complete. In partial duplication, the ureters join above the bladder and there is 1 ureteral orifice. In complete duplication, the attachment of the lower pole ureter to the bladder is superior and lateral to the upper pole ureter. The valve-like mechanism for the lower pole ureter often is marginal, and VUR into the lower ureter occurs in as many as 50% of cases. VUR occurs into both the lower and upper systems in some persons (Fig. 539-5). With a duplication anomaly, some patients have an ectopic ureter, in which the upper pole ureter drains outside the bladder (see Chapters 540 and 543 and Figs. 543-6 and 543-7). If the ectopic ureter drains into the bladder neck, typically it is obstructed and reflexes. Duplication anomalies also are common in children with a ureterocele, which is a cystic swelling of the intramural portion of the distal ureter. These patients often have VUR into the associated lower pole ureter or the contralateral ureter. In addition, generally VUR is present when the ureter enters a bladder diverticulum (Fig. 539-6).

VUR is present at birth in 25% of children with neuropathic bladder, as occurs in myelomeningocele (see Chapter 591.4), sacral agenesis, and many cases of high imperforate anus. VUR is seen in 50% of boys with posterior urethral valves. VUR with increased intravesical pressure (as in detrusor–sphincter dyssynergia or bladder outlet obstruction) can result in renal injury because of increased intravesical pressure transmitted to the upper urinary tract, even in the absence of infection.

Primary VUR occurs in association with several congenital urinary tract abnormalities. Of children with a multicystic dysplastic kidney or renal agenesis (see Chapter 537), 15% have VUR into the contralateral kidney, and 10-15% of children with a ureteropelvic junction obstruction have VUR into either the hydronephrotic kidney or the contralateral kidney.

Figure 539-6 VUR and bladder diverticulum. The voiding cystourethrogram demonstrates left vesicoureteral reflux and a paraureteral diverticulum.
VUR (idiopathic) appears to be an autosomal dominant inherited trait with variable penetrance. Approximately 35% of siblings of children with VUR also have VUR, and VUR is found in nearly half of newborn siblings. The likelihood of a sibling having VUR is independent of the grade of VUR or sex of the index child. Approximately 12% of asymptomatic siblings with VUR have evidence of renal scarring. In addition, 50% of children born to women with a history of VUR also have VUR. In 2010 the American Urological Association Vesicoureteral Reflux Guidelines Panel stated that, in siblings of individuals with VUR, a VCUG or radionuclide cystogram is recommended if there is evidence of renal cortical abnormalities or renal size asymmetry on sonography, or if the sibling has a history of UTI. Otherwise, screening is optional. VUR may be suggested on a prenatal ultrasound, which demonstrates dilated renal calyces. Primary VUR is uncommon in African-Americans.

**CLINICAL MANIFESTATIONS**

VUR usually is discovered during evaluation for a UTI (see Chapter 538). Among these children, 80% are female, and the average age at diagnosis is 2-3 yr. In other children, a VCUG is performed during evaluation of bladder–bowel dysfunction, renal insufficiency, hypertension, or other suspected pathologic process of the urinary tract. Primary VUR also may be discovered during evaluation for antenatal hydronephrosis. In this select population, 80% of affected children are male, and the VUR grade usually is higher than in girls whose VUR is diagnosed following a UTI. The UTI may be symptomatic, an isolated febrile event, or more often both febrile and symptomatic (abdominal pain, dysuria, etc.). Bladder and bowel dysfunction (constipation) may be present in 50% of children with reflux and a UTI.

**DIAGNOSIS**

Diagnosis of VUR requires catheterization of the bladder, instillation of a solution containing iodinated contrast or a radiopharmaceutical, and radiologic imaging of the lower and upper urinary tract: a contrast VCUG or radionuclide cystogram, respectively. The bladder and upper urinary tracts are imaged during bladder filling and voiding. VUR occurring during bladder filling is termed low-pressure VUR; VUR during voiding is termed high-pressure VUR. VUR in children with low-pressure VUR is significantly less likely to resolve spontaneously than in children who exhibit only high-pressure VUR. Radiation exposure during a radionuclide cystogram is significantly less than that from a contrast VCUG. However, the contrast VCUG provides more anatomic information, such as demonstration of a duplex collecting system, ectopic ureter, paraureteral (bladder) diverticulum, bladder outlet obstruction in boys, upper urinary tract stasis, and signs of voiding dysfunction, such as a “spinning top” urethra in girls. The VUR grading system is based on the appearance on contrast VCUG, and the grade reported is the maximum grade observed during the study. For follow-up evaluation, some prefer the radionuclide cystogram because of the lower radiation exposure (Fig. 539-7), although it is difficult to determine whether the VUR severity has changed.

Children undergoing cystography may be psychologically traumatized by the catheterization. Careful preparation by caregivers, use of Child Life individuals, or administration of oral or nasal midazolam (for sedation and amnesia) or propofol before the study can result in a less-distressing experience.

**Indirect cystography** is a technique of detecting VUR without catheterization that involves injecting an intravenous radiopharmaceutical that is excreted by the kidneys, waiting for it to be excreted into the bladder, and imaging the lower urinary tract while the patient voids. This technique detects only 75% of VUR cases. Another technique, which avoids radiation exposure, involves instilling sonographic contrast medium through a urethral catheter. The kidneys are imaged sonographically to determine whether any of the material refluxes. This technique is investigational.

After VUR is diagnosed, assessment of the upper urinary tract is important. The goal of upper tract imaging is to assess whether renal scarring and associated urinary tract anomalies are present. Renal imaging typically is performed with a renal sonogram or renal scintigraphy (Fig. 539-8; see Chapter 538).

The child should be evaluated for bladder–bowel dysfunction, including urgency, frequency, diurnal incontinence, infrequent voiding, pain, dysuria, etc.). Bladder and bowel dysfunction (constipation) may be present in 50% of children with reflux and a UTI.
or a combination of these (see Chapter 543). Children with an overactive bladder often undergo a regimen of behavioral modification with timed voiding, and, on occasion, anticholinergic therapy.

After diagnosis, the child’s height, weight, and blood pressure should be measured and monitored. If upper tract imaging shows renal scarring, a serum creatinine measurement should be obtained. The urine should be assessed for infection and proteinuria.

**Natural History**

The incidence of reflux-related renal scarring increases with VUR grade. With bladder growth and maturation, the VUR grade often resolves or improves. Lower grades of VUR are much more likely to resolve than are higher grades. For grades I and II VUR, the likelihood of resolution is similar regardless of age at diagnosis and whether it is unilateral or bilateral. For grade III, a younger age at diagnosis and unilateral VUR usually are associated with a higher rate of spontaneous resolution (Fig. 539-9). Bilateral grade IV VUR is much less likely to resolve than is unilateral grade IV VUR. Grade V VUR rarely resolves. The mean age at VUR resolution is 6 yr.

VUR does not usually cause renal injury in the absence of infection, but in situations with high-pressure VUR, as in children with posterior urethral valves, neuropathic bladder, and nonneurogenic neurogenic bladder (i.e., Hinman syndrome), sterile VUR can cause significant renal damage. Children with high-grade VUR who acquire a UTI are at significant risk for acute and recurrent pyelonephritis and new renal scarring (see Fig. 539-8).

**Treatment**

The goals of treatment are to prevent pyelonephritis, VUR-related renal injury, and other complications of VUR. Medical therapy is based on the principle that VUR often resolves over time and that if UTIs can be prevented, the morbidity or complications of VUR may be avoided without surgery. Medical therapy includes observation with behavioral modification or behavioral modification with antimicrobial prophylaxis in some patients. The basis for surgical therapy is that in selected children, ongoing VUR has caused or has significant potential for causing renal injury or other VUR-related complications, and that elimination of VUR minimizes the risk of these problems. Therapy for VUR should be individualized based on a particular patient’s risk factors.

**Observation**

In children undergoing observation, therapeutic emphasis is directed to minimizing the risk of UTI by behavioral modification. These methods include timed voiding during the day, ensuring regular fecal elimination, increased fluid intake, periodic assessment of satisfactory bladder emptying, and prompt assessment and treatment of UTIs, particularly febrile UTIs. This approach is most appropriate for children with grades I and II VUR, and perhaps older children with persistent VUR and normal kidneys who have not experienced clinical pyelonephritis.

**Antimicrobial Prophylaxis**

In the past, based on clinical series demonstrating the effectiveness of antibiotic prophylaxis and the 1997 American Urological Association (AUA) Reflux Guidelines, daily prophylaxis was recommended as initial therapy for most children with VUR. Currently, many families express concern regarding the safety and benefit of prophylaxis. In addition, as a result of several prospective clinical trials, the benefit of prophylaxis has been questioned in children with VUR. The risk of recurrent UTI is highest in patients with grade III or IV reflux, those with bowel and bladder dysfunction, and those whose first reflux associated UTI was febrile rather than just symptomatic without fever. Antibiotic prophylaxis after a reflux associated UTI decreases the risk of recurrent UTI but increases the risk of developing resistant bacteria. In one study, antibiotic prophylaxis reduced the risk of new renal scars in children with grade III or IV reflux; while in another larger study antibiotic prophylaxis did not have an effect on the incidence of new renal scars in those with severe reflux (approximately 10% developed new scars regardless of prophylaxis).

**Surgery**

The purpose of surgical therapy is to minimize the risks of ongoing VUR and nonsurgical therapy (prophylaxis and follow-up testing). VUR can be corrected through a lower abdominal or inguinal incision (open), laparoscopically (with or without robotic assistance), or endoscopically with subureteral injection.

Open surgical management involves modifying the abnormal ureterovesical attachment to create a 4:1 to 5:1 ratio of intramural ureter length:ureteral diameter. The operation can be performed from either outside or inside the bladder. When VUR is associated with severe ureteral dilation (i.e., megareter), the ureter must be tailored or narrowed to a more normal size to allow a smaller length:width ratio for the intramural tunnel, and a corner of the bladder is attached to the psoas tendon, forming a *psoas hitch*. Most children can be discharged 1-2 days following the surgical procedure. If the refluxing kidney is poorly functioning, nephrectomy or nephroureterectomy is indicated. Laparoscopic VUR correction and robotic-assisted laparoscopic ureteral reimplantation have been investigated and have been shown to have similar results to conventional open surgery in older children.

The success rate of conventional open ureteral reimplantation in children with primary VUR is >95-98% for grades I-IV, with 2% experiencing persistent VUR and 1% having ureteral obstruction that requires correction. The success rate is so high that many pediatric urologists do not perform a postoperative VCUG unless the child develops clinical pyelonephritis. For grade V VUR, the success rate is

---

**Figure 539-9** A, Percentage chance of VUR persistence, grades I, II, and IV, for 1-5 yr after presentation. B, Percentage chance of VUR persistence by age at presentation, grade III, for 1-5 yr after presentation. (From Elder JS, Peters CA, Arant BS Jr, et al: Pediatric Vesicoureteral Reflux Guidelines Panel summary report on the management of primary vesicoureteral reflux in children, J Urol 157:1846–1851, 1997.)
approximately 80%. In lower grades of VUR, a failed reimplantation is most likely to occur in children with undiagnosed bladder-bowel dysfunction. In children with secondary VUR (posterior urethral valves, neuropathic bladder), the success rate is slightly lower than with primary VUR. The risk of pyelonephritis in children with grades III and IV VUR is significantly lower following open surgical correction compared with medical management. Surgical repair will not reverse renal scarring or cause improvement in renal function.

Endoscopic repair of VUR involves injection of a bulking agent through a cystoscope just beneath the ureteral orifice, creating an artificial flap-valve (Figs. 539-10 and 539-11). In 2001, the FDA approved the use of a biodegradable material, dextranomer microspheres suspended in hyaluronic acid (Deflux), for subureteral injection. The advantage of subureteral injection is that it is a noninvasive outpatient procedure (performed under general anesthesia) with no recovery time. The success rate is 70-80% and is highest for lower grades of VUR. If the first injection is unsuccessful, 1 or 2 repeat injections can be performed. The VUR recurrence rate is approximately 10%.

**Current Vesicoureteral Reflux Guidelines**

In 2010 the AUA provided updated evidence-based guidelines regarding VUR management, and in 2012 the European Association of Urology published expert opinion based guidelines. Both society recommendations were based on risk assessment of children with VUR.

The long-standing belief regarding the benefit of antibiotic prophylaxis in children with VUR has been questioned. Multiple randomized controlled prospective trials suggested that the risk of UTI in children with VUR is not reduced by prophylaxis. Most of the children in these trials had grades I-III VUR, and few younger than 1 yr old were studied. In contrast, the PRIVENT (Prevention of Recurrent Urinary Tract Infection in Children with Vesicoureteric Reflux and Normal Renal Tracts) trial from Australia showed significant benefit to prophylaxis in children with VUR. The Swedish VUR Trial in Children studied children younger than 2 yr of age with grades III and IV VUR; they compared antibiotic prophylaxis to observation and endoscopic injection therapy. Girls in the surveillance group had a significantly higher incidence of febrile UTI and new renal scarring compared to the other treatment groups. The largest randomized trial (RIVUR [Randomized Intervention for Children with Vesicoureteral Reflux]) enrolled more than 600 children and demonstrated a reduction in the recurrence rate of UTIs but no reduction of the occurrence of renal scarring with antibiotic prophylaxis.

Prophylaxis is recommended by the AUA in children at greatest risk for VUR-related renal injury (i.e., those younger than 1 yr of age). In addition, evaluation for bladder and bowel dysfunction is considered a standard part of initial and ongoing patient evaluation in children with VUR. Because children with bladder and bowel dysfunction and VUR are much more likely to have recurrent UTIs and renal scarring, prophylaxis is recommended for these children. In children with VUR who are being managed by surveillance, if a febrile UTI occurs, prophylaxis is recommended. The decision whether to recommend observation, medical therapy, or surgery is based on the risk of VUR to the patient, the likelihood of spontaneous resolution, and the parents’ and patient’s preferences, and the family should understand the risks and benefits of each treatment approach.

Another aspect of VUR management pertains to screening. VUR is known to be a familial disorder with autosomal dominant transmission with variable penetrance. The advantage of early VUR detection is to implement treatment before a potentially damaging episode of clinical pyelonephritis. In siblings of an index patient with VUR, optional management includes screening of asymptomatic siblings or offspring with a renal ultrasound or VCUG. The AUA recommends that a VCUG should be obtained if a screening ultrasound demonstrated a renal abnormality or if the sibling had a UTI.
The AUA also determined that female newborns with renal pelvic dilation were significantly more likely than male newborns to have VUR. The AUA recommended that a VCUG should be performed in neonates with grade 3-4 antenatal hydronephrosis (moderate to severe pelvocaliceal dilation), hydroureter, or an abnormal bladder. In children with less-severe renal pelvic dilation, an observational approach without screening for VUR, with prompt treatment of any UTI, is appropriate. However, they also indicated that obtaining a VCUG is considered an appropriate option for neonates with lesser grades of hydronephrosis.

Chapter 540
Obstruction of the Urinary Tract
Jack S. Elder

Most childhood obstructive lesions are congenital, although urinary tract obstruction can be caused by trauma, neoplasia, calculi, inflammatory processes, or surgical procedures. Obstructive lesions occur at any level from the urethral meatus to the calyceal infundibula (Table 540-1). The pathophysiologic effects of obstruction depend on its level, the extent of involvement, the child’s age at onset, and whether it is acute or chronic.

ETIOLOGY
Ureteral obstruction occurring early in fetal life results in renal dysplasia, ranging from multicystic kidney, which is associated with ureteral or pelvic atresia (see Fig. 537-2 in Chapter 537), to various degrees of histologic renal cortical dysplasia that are seen with less-severe obstruction. Chronic ureteral obstruction in late fetal life or after birth results in dilation of the ureter, renal pelvis, and calyces, with alterations of renal parenchyma ranging from minimal tubular changes to dilation of Bowman’s space, glomerular fibrosis, and interstitial fibrosis. After birth, infections often complicate obstruction and can increase renal damage.

Prenatal screening with ultrasonography may detect antenatal hydronephrosis, which is graded by the trimester and the anterior-posterior diameter of the renal pelvis (Table 540-2); most are mild. Table 540-3 notes the eventual etiology.

CLINICAL MANIFESTATIONS
Obstruction of the urinary tract generally causes hydronephrosis, which typically is asymptomatic in its early phases. An obstructed kidney secondary to a ureteropelvic junction (UPJ) or ureterovesical junction obstruction can manifest as a unilateral mass or cause upper abdominal or flank pain on the affected side. Pyelonephritis can occur because of urinary stasis. An upper urinary tract stone can occur, causing abdominal and flank pain and hematuria. With bladder outlet obstruction, the urinary stream may be weak; urinary tract infection (UTI; see Chapter 538) is common. Many of these lesions are identified by antenatal ultrasonography; an abnormality involving the genitourinary tract is suspected in as many as 1 in 100 fetuses.

Obstructive renal insufficiency can manifest itself by failure to thrive, vomiting, diarrhea, or other nonspecific signs and symptoms. In older children, infravesical obstruction can be associated with overflow urinary incontinence or a poor urine stream. Acute ureteral obstruction causes flank or abdominal pain; there may be nausea and vomiting. Chronic ureteral obstruction can be silent or can cause vague abdominal or typical flank pain with increased fluid intake.

**DIAGNOSIS**

Urinary tract obstruction may be diagnosed prenatally by ultrasonography, which typically shows hydronephrosis and occasionally a distended bladder. More complete evaluation, including imaging studies, should be undertaken in these children in the neonatal period.

Urinary tract obstruction is often silent. In the newborn infant, a palpable abdominal mass most commonly is a hydronephrotic or multicystic dysplastic kidney. With posterior urethral valves, which is an infravesical obstructive lesion in boys, a walnut-sized mass representing the bladder is palpable just above the pubic symphysis. A patent draining urachus also can suggest urethral obstruction. Urinary ascites in the newborn usually is caused by renal or bladder urinary extravasation secondary to posterior urethral valves. Infection and sepsis may be the first indications of an obstructive lesion of the urinary tract. The combination of infection and obstruction poses a serious threat to infants and children and generally requires parenteral administration of antibiotics and drainage of the obstructed kidney. Renal ultrasonography should be performed in all children during the acute stage of an initial febrile UTI.

**Imaging Studies**

**Renal Ultrasonography**

Hydronephrosis is the most common characteristic of obstruction (Fig. 540-1). Upper urinary tract dilation is not diagnostic of obstruction and often persists after surgical correction of a significant obstructive lesion. Dilation can result from vesicoureteral reflux, or it may be a manifestation of abnormal development of the urinary tract, even when there is no obstruction. Renal length, degree of caliectasis and parenchymal thickness, and presence or absence of ureteral dilation should be assessed. Most pediatric urologists grade the severity of hydronephrosis from 1-4 using the Society for Fetal Urology grading scale (Table 540-4), whereas pediatric radiologists generally utilize the adjectives mild, moderate, and severe. The clinician should ascertain that the contralateral kidney is normal, and the bladder should be imaged to see whether the bladder wall is thickened, the lower ureter is dilated, and bladder emptying is complete. In acute or intermittent obstruction, the dilation of the collecting system may be minimal and ultrasonography may be misleading.

**Voiding Cystourethrogram**

In neonates and infants with congenital grade 3 or 4 hydronephrosis and in any child with ureteral dilation, a contrast voiding cystourethrogram (VCUG) should be obtained, because the dilation is secondary to vesicoureteral reflux in 15% of cases. In boys, the VCUG also is performed to rule out urethral obstruction, particularly in cases of suspected posterior urethral valves. In older children, the urinary flow rate can be measured noninvasively with a urinary flowmeter; decreased flow with a normal bladder contraction suggests infravesical obstruction (e.g., posterior urethral valves, urethral stricture). When the urethra cannot be catheterized to obtain a VCUG, the clinician should suspect a urethral stricture or an obstructive urethral lesion. Retrograde urethrogram with contrast medium injected into the urethral meatus helps delineate the anatomy of the urethral obstruction.

**Radioisotope Studies**

Renal scintigraphy is used to assess renal anatomy and function. The 2 most commonly used radiopharmaceuticals are mercaptoacetyl triglycine (MAG-3) and technetium-99m-labeled dimercaptosuccinic acid. MAG-3, which is excreted by renal tubular secretion, is used to assess differential renal function, and when furosemide is administered, drainage also can be measured. An alternative to MAG-3 is diethylene tetrapiacet acid, which is cleared by glomerular filtration. The background activity of diethylene tetrapiacet acid is much higher than that of MAG-3. Dimercaptosuccinic acid is a renal cortical imaging agent and is used to assess differential renal function and to demonstrate whether renal scarring is present. It is used infrequently in children with obstructive uropathy.

In a MAG-3 diuretic renogram, a small dose of technetium-labeled MAG-3 is injected intravenously (Figs. 540-2 and 540-3). During the 1st 2-3 min, renal parenchymal uptake is analyzed and compared, allowing computation of differential renal function. Subsequently,

*Figure 540-1 Ultrasonographic image of the kidney with marked pelvic and calyceal dilation (grade 4 hydronephrosis) in a newborn with ureteropelvic junction obstruction.*
Magnetic Resonance Urography

MR urography is also used to evaluate suspected upper urinary tract pathology. The child is hydrated and given intravenous furosemide. Gadolinium-diethylene tetrapentaacetic acid is injected and routine T1-weighted and fat-suppressed fast spin-echo T2-weighted imaging is performed through the kidneys, ureters, and bladder. This study provides superb images of the pathology, and methodology permits assessment of differential renal function and drainage (Fig. 540-4).

There is no radiation exposure; however, young children need sedation or anesthesia. It is used primarily when renal sonography and nuclear imaging fail to delineate complex pathology.

Computed Tomography

In children with a suspected ureteral calculus, noncontrast spiral CT of the abdomen and pelvis is a standard method of demonstrating whether a calculus is present, its location, and whether there is significant proximal hydronephrosis. This study is the initial study of choice in many of these patients. The disadvantage of CT is the significant radiation exposure, and it should be used only when the results will direct management decisions (see Chapter 718).

Ancillary Studies

In unusual cases, an antegrade pyelogram (insertion of a percutaneous nephrostomy tube and injection of contrast agent), can be performed to assess the anatomy of the upper urinary tract. This procedure usually requires general anesthesia. In addition, an antegrade pressure-perfusion flow study (Whitaker test) may be performed, in which fluid is infused at a measured rate, usually 10 mL/min. The pressures...

Excretory Urogram

Excretory urogram is rarely used in assessing the pediatric urinary tract, although it may be useful in selected cases with indeterminate upper urinary tract obstruction or a suspected duplication anomaly.
Ureteropelvic Junction Obstruction

UPJ obstruction is the most common obstructive lesion in childhood and usually is caused by intrinsic stenosis (see Figs. 540-1 to 540-3). An accessory artery to the lower pole of the kidney also can cause extrinsic obstruction. The typical appearance on ultrasonography is grade 3 or 4 hydronephrosis without a dilated ureter. UPJ obstruction most commonly manifests on antenatal sonography revealing fetal hydronephrosis; as a palpable renal mass in a newborn or infant; as abdominal, flank, or back pain; as a febrile UTI; or as hematuria after minimal trauma. Approximately 60% of cases occur on the left side, and the male:female ratio is 2:1. UPJ obstruction is bilateral in only 10% of cases. In kidneys with UPJ obstruction, renal function may be significantly impaired from pressure atrophy, but approximately half of affected kidneys have relatively normal glomerular function. The anomaly is corrected by performing a pyeloplasty, in which the stenotic segment is excised and the normal ureter and renal pelvis are reattached. Success rates are 91-98%. Pyeloplasty can be performed using laparoscopic techniques, often robotic-assisted using the da Vinci robot.

Lesser degrees of UPJ narrowing might cause mild hydronephrosis, which usually is nonobstructive, and typically these kidneys function normally. The spectrum of UPJ abnormalities has been referred to as anomalous UPJ. Another cause of mild hydronephrosis is fetal folds of the upper ureter, which also are nonobstructive.

The diagnosis can be difficult to establish in an asymptomatic infant in whom dilation of the renal pelvis is found incidentally in a prenatal ultrasonogram. After birth, the sonographic study is repeated to confirm the prenatal finding. A VCUG is necessary because 10-15% of patients have ipsilateral vesicoureteral reflux. Because neonatal oliguria can cause temporary decompression of a dilated renal pelvis, it is ideal to perform the first postnatal sonogram after the 3rd day of life. Delaying the sonogram may be impractical. If no dilation is found on the initial sonogram, a repeat study should be performed at 1 mo of age. If the kidney shows grade 1 or 2 hydronephrosis and the renal parenchyma appears normal, a period of observation usually is appropriate, with sequential renal ultrasonograms to monitor the severity of hydronephrosis, and the hydronephrosis usually disappears. Antibiotic prophylaxis is not indicated for children with mild hydronephrosis. If the hydronephrosis is grade 3 or 4, spontaneous resolution is less likely and obstruction is more likely to be present, particularly if the renal pelvic diameter is 3 cm. A diuretic renogram with MAG-3 is performed at 4-6 wk of age. If there is poor upper tract drainage or the differential renal function is poor, pyeloplasty is recommended. After pyeloplasty the differential renal function often improves, and improved drainage with furosemide stimulation is expected.

If the differential function on renography is normal, and drainage is satisfactory, the infant can be followed with serial ultrasonograms, even with grade 4 hydronephrosis. If the hydronephrosis remains severe with no improvement, a repeat diuretic renogram after 6-12 mo can help in the decision between continued observation and surgical repair. Prompt surgical repair is indicated in infants with an abdominal mass, bilateral severe hydronephrosis, a solitary kidney, or diminished function in the involved kidney. In unusual cases in which the differential renal function is <10% but the kidney definitely has some function, insertion of a percutaneous nephrostomy tube allows drainage of the hydronephrotic kidney for a few weeks to allow reassessment of renal function. In older children who present with symptoms, the diagnosis of UPJ obstruction usually is established by ultrasonography and diuretic renography.
The following entities should be considered in the differential diagnosis: megacalycosis, a congenital nonobstructive dilation of the calyces without pelvic or ureteric dilation; vesicoureteral reflux with marked dilation and kinking of the ureter; midureteral or distal ureteral obstruction when the ureter is not well visualized on the urogram; and retrocaval ureter.

**Midureteral Obstruction**
Congenital ureteral stenosis or a ureteral valve in the midureter is rare. It is corrected by excision of the strictured segment and reanastomosis of the normal upper and lower ureteral segments. A retrocaval ureter is an anomaly in which the upper right ureter travels posterior to the inferior vena cava. In this anomaly, the vena cava can cause extrinsic compression and obstruction. An IVP or MR urogram shows the right ureter to be medially deviated at the level of the 3rd lumbar vertebra. The diagnosis may be confirmed by retrograde pyelography (see Fig. 540-5). Surgical treatment consists of transection of the upper ureter, moving it anterior to the vena cava, and reanastomosing the upper and lower segments. Repair is necessary only when obstruction is present. Retroperitoneal tumors, fibrosis caused by surgical procedures, inflammatory processes (as in chronic granulomatous disease), and radiation therapy can cause acquired midureteral obstruction.

**Ectopic Ureter**
A ureter that drains outside the bladder is referred to as an ectopic ureter. This anomaly is 3 times as common in girls as in boys and usually is detected prenatally. The ectopic ureter typically drains the upper pole of a duplex collecting system (2 ureters).

In girls, approximately 35% of these ureters enter the urethra at the bladder neck, 35% enter the urethrovaginal septum, 25% enter the vagina, and a few drain into the cervix, uterus, Gartner duct, or a urethral diverticulum. Often the terminal aspect of the ureter is narrowed, causing hydroureteronephrosis. With the exception of the ectopic ureter entering the bladder neck, in girls an ectopic ureter causes continuous urinary incontinence from the affected renal moiety. UTI is common because of urinary stasis.

In boys, ectopic ureters enter the posterior urethra (above the external sphincter) in 47%, the prostatic utricle in 10%, the seminal vesicle in 33%, the ejaculatory duct in 5%, and the vas deferens in 5%. Consequently, in boys, an ectopic ureter does not cause incontinence, and most patients present with a UTI or epididymitis.

Evaluation includes a renal sonogram, VCUG, and renal scan, which demonstrates whether the affected segment has significant function. The sonogram shows the affected hydronephrotic kidney or dilated upper pole and ureter down to the bladder (Fig. 540-6). If the ectopic ureter drains into the bladder neck (female), a VCUG usually shows reflux into the ureter. Otherwise, there is no reflux into the ectopic ureter, but there may be reflux into the ipsilateral lower pole ureter or contralateral collecting system.

**Treatment** depends on the status of the renal unit drained by the ectopic ureter. If there is satisfactory function, ureteral reimplantation into the bladder or ureteroureterostomy (anastomosing the ectopic upper pole ureter into the normally inserting lower pole ureter) is indicated. If function is poor, partial or total nephrectomy is indicated. In many centers this procedure is done laparoscopically and often with robotic assistance using the da Vinci robot.

**Ureterocele**
A ureterocele is a cystic dilation of the terminal ureter and is obstructive because of a pinpoint ureteral orifice. Ureteroceles are much more common in girls than in boys. Affected children usually are discovered by prenatal ultrasonography, but some present with a febrile UTI. Ureteroceles may be ectopic, in which case the cystic swelling extends through the bladder neck into the urethra, or orthotopic, in which case the ureterocele is entirely within the bladder. Both orthotopic and ectopic ureteroceles can be bilateral.

In girls, ureteroceles nearly always are associated with ureteral duplication (Fig. 540-7), whereas in 50% of affected boys there is only 1

---

**Figure 540-7**
A, Infant with ectopic ureterocele. Sonogram of the left kidney shows massive dilation of the upper pole and a normal lower pole. B, Voiding cystourethrogram shows large ureterocele, draining the left upper pole, in the bladder. No reflux is present.

**Figure 540-6** Ultrasoundographic image of the right dilated ureter (bottom arrows) extending behind and caudal to a nearly empty bladder (top arrow) in a girl with urinary incontinence and ectopic ureter draining into the vagina.
ureter. When associated with a duplication anomaly, the ureterocele drains the upper renal moiety, which commonly functions poorly or is dysplastic because of congenital obstruction. The lower pole ureter drains into the bladder superior and lateral to the upper pole ureter and may reflux.

An ectopic ureterocele extends submucosally into the urethra. Rarely, large ectopic ureteroceles can cause bladder outlet obstruction and retention of urine with bilateral hydroureteronephrosis. In girls, the ureterocele can prolapse from the urethral meatus. Ultrasonography is effective in demonstrating the ureterocele and whether the associated obstructed system is duplicated or single. VCUG usually shows a filling defect in the bladder, sometimes large, corresponding to the ureterocele, and it often shows reflux into the adjacent lower pole collecting system with typical findings of a “drooping lily” appearance to the kidney. Nuclear renal scintigraphy is most accurate in demonstrating whether the affected renal moiety has significant function.

Treatment of ectopic ureteroceles varies among different medical centers and depends on whether the upper pole functions on renal scan and whether there is reflux into the lower pole ureter. If there is nonfunction of the upper pole of the kidney and there is no reflux, treatment usually involves laparoscopic, robotic, or open excision of the obstructed upper pole and most of the associated ureter. If there is function in the upper pole or significant reflux into the lower pole ureter, or if the patient is septic from infection of the hydrourephrotic kidney, then transurethral incision with cautery is appropriate initial therapy to decompress the ureterocele. Reflux into the incised ureterocele is common, and subsequent excision of the ureterocele and ureteral reimplantation usually is necessary. An alternative method is to perform a upper-to-lower ureteroureterostomy, allowing the obstructed upper pole ureter to drain through the normal lower ureter; this procedure often is performed with minimally invasive laparoscopic (robotic) technique or through a small incision.

Orthotopic ureteroceles are associated with duplicated or single collecting systems, and the orifice is in the expected location in the bladder (Fig. 540-8). These anomalies usually are discovered during an investigation for prenatal hydronephrosis or a UTI. Ultrasonography is sensitive for detecting the ureterocele in the bladder and hydroureteronephrosis. IVP reveals varying degrees of ureteral and calyceal dilation, and there is a round filling defect in the bladder. In delayed films, cystic dilation of the ureter may be clearly visible and full of contrast material. Transurethral incision of the ureterocele effectively relieves the obstruction, but it can result in vesicoureteral reflux, necessitating ureteral reimplantation later. Some prefer open excision of the ureterocele and reimplantation as the initial form of treatment. Small, simple ureteroceles discovered incidentally without upper tract dilation generally do not require treatment.

Megaureter

Table 540-5 presents a classification of megaureters (dilated ureter). Numerous disorders can cause ureteral dilation, and many are nonobstructive.

Megaureters usually are discovered during antenatal sonography, postnatal U/UTI, hematoma, or abdominal pain. A careful history, physical examination, and VCUG identify causes of secondary megaureters and refluxing megaureters as well as the prune-belly syndrome. Primary obstructed megaureters and nonobstructed megaureters probably represent varying degrees of severity of the same anomaly.

The primary obstructed nonrefluxing megaureter results from abnormal development of the distal ureter, with collagenous tissue replacing the muscle layer. Normal ureteral peristalsis is disrupted, and the proximal ureter widens. In most cases there is not a true stricture. On IVP or an MR urogram, the distal ureter is more dilated in its distal segment and tapers abruptly at or above the junction of the bladder (Fig. 540-9). The lesion may be unilateral or bilateral. Significant hydroureteronephrosis suggests obstruction. Megaureter predisposes to UTI, urinary stones, hematuria, and flank pain because of urinary stasis. In most cases, diuretic renography and sequential sonographic studies can reliably differentiate obstructed from nonobstructed megaureters. In most nonobstructed megaureters, the hydroureteronephro-

Figure 540-8 Simple intravesical ureterocele. The excretory urogram shows left hydronephrosis and a round filling defect on the left side of the bladder corresponding to a simple ureterocele causing left ureteral obstruction. This lesion was treated by transurethral incision and drainage of the ureterocele.
Obstructed Classification of Megaureter

Nonrefluxing and Nonobstructed diagnosis of obstruction was confirmed by diuretic renography. The predominant dilation of the distal ureter. Note the characteristic urogram in a girl with a history of a febrile urinary tract infection. The development end-stage renal disease from dysplasia or complications of pulmonary hypoplasia. As many as 30% of the long-term survivors syndrome are stillborn or die in the 1st few mo of life because of pulmonoplasia and renal dysplasia. One third of children with prune-belly and functional benefits. 1st 6 located high in the abdomen and surgery is best accomplished in the orchidopexy can be difficult in these children because the testes are many neonates with prune-belly syndrome have difficulty with effective bladder emptying because the bladder musculature is poorly developed, and the urethra may be narrowed. When no obstruction is present, the goal of treatment is the prevention of UTI with antibiotic prophylaxis. When obstruction of the ureters or urethra is demonstrated, temporary drainage procedures, such as a vesicostomy, can help to preserve renal function until the child is old enough for surgery. Some children with prune-belly syndrome have been found to have classic or atypical posterior urethral valves. UTIs occur often and goes unrecognized during the neonatal period, infants can present, the goal of treatment is the prevention of UTI with antibiotic prophylaxis. When obstruction of the ureters or urethra is demonstrated, temporary drainage procedures, such as a vesicostomy, can help to preserve renal function until the child is old enough for surgery. Some children with prune-belly syndrome have been found to have classic or atypical posterior urethral valves. UTIs occur often and should be treated promptly. Correction of the undescended testes by orchidopexy can be difficult in these children because the testes are located high in the abdomen and surgery is best accomplished in the 1st 6 mo of life. Reconstruction of the abdominal wall offers cosmetic and functional benefits. The prognosis ultimately depends on the degree of pulmonary hypoplasia and renal dysplasia. One third of children with prune-belly syndrome are stillborn or die in the 1st few mo of life because of pulmonary hypoplasia. As many as 30% of the long-term survivors develop end-stage renal disease from dysplasia or complications of infection or reflux and eventually require renal transplantation. Renal transplantation in these children offers good results.

Bladder Neck Obstruction

Bladder neck obstruction usually is secondary to ectopic ureterocele, bladder calculi, or a tumor of the prostate (rhabdomyosarcoma). The manifestations include difficulty voiding, urinary retention, UTI, and bladder distention with overflow incontinence. Apparent bladder neck obstruction is common in cases of posterior urethral valves, but it seldom has any functional significance. Primary bladder neck obstruction is extremely rare.

Posterior Urethral Valves

The most common cause of severe obstructive uropathy in children is posterior urethral valves, affecting 1 in 8,000 boys. The urethral valves are tissue leaflets fanning distally from the prostatic urethra to the external urinary sphincter. A slit-like opening usually separates the leaflets. Valves are of unclear embryologic origin and cause varying degrees of obstruction. Approximately 30% of patients experience end-stage renal disease or chronic renal insufficiency. The prostatic urethra dilates, and the bladder muscle undergoes hypertrophy. Vesicoureteral reflux occurs in 50% of patients, and distal ureteral obstruction can result from a chronically distended bladder or bladder muscle hyper trophy. The renal changes range from mild hydronephrosis to severe renal dysplasia; their severity probably depends on the severity of the obstruction and its time of onset during fetal development. As in other cases of obstruction or renal dysplasia, there may be oligohydramnios and pulmonary hypoplasia.

Affected boys with posterior urethral valves often are discovered prenatally when maternal ultrasonography reveals bilateral hydro nephrosis, a distended bladder, and, if the obstruction is severe, oligohydramnios. Prenatal bladder decompression by percutaneous vesicoamniotic shunt or open fetal surgery has been reported. Experimental and clinical evidence of the possible benefits of fetal intervention is lacking, and few affected fetuses are candidates. Prenatally diagnosed posterior urethral valves, particularly when discovered in the 2nd trimester, carry a poorer prognosis than those detected in the 3rd trimester following a normal second fetal ultrasound. In the male neonate, posterior urethral valves are suspected when there is a palpably distended bladder and the urinary stream is weak. If the obstruction is severe and goes unrecognized during the neonatal period, infants can present later in life with failure to thrive because of uremia or sepsis caused by infection in the obstructed urinary tract. With lesser degrees of obstruction, children present later in life with difficulty in achieving diurnal urinary continence or with UTI. The diagnosis is established with a VCUG (Fig. 540-12) or by perineal ultrasonography.

After the diagnosis is established, renal function and the anatomy of the upper urinary tract should be carefully evaluated. In the healthy neonate, a small polyethylene feeding tube (No. 5 or No. 8 French) is inserted in the bladder and left for several days. Passing the feeding
Favorable prognostic factors include a normal prenatal ultrasonogram between 18 and 24 wk of gestation, a serum creatinine level <0.8-1.0 mg/dL after bladder decompression, and visualization of the corticomedullary junction on renal sonography. In several situations, a "popoff valve" can occur during urinary tract development, which preserves the integrity of 1 or both kidneys. For example, 15% of boys with posterior urethral valves have unilateral reflux into a nonfunctioning dysplastic kidney, termed the VURD syndrome (valves, unilateral reflux, dysplasia). In these boys, the high bladder pressure is dissipated into the nonfunctioning kidney, allowing normal development of the contralateral kidney. In newborn boys with urinary ascites, the urine generally leaks out from the obstructed collecting system through the renal fornices, allowing normal development of the kidneys. Unfavorable prognostic factors include the presence of oligohydramnios in utero, identification of hydronephrosis before 24 wk of gestation, a serum creatinine level >1.0 mg/dL after bladder decompression, identification of cortical cysts in both kidneys, and persistence of diurnal incontinence beyond 5 yr of age.

If the serum creatinine level remains high or increases despite bladder drainage by a small catheter, secondary ureteral obstruction, irreversible renal damage, or renal dysplasia should be suspected. In such cases, a vesicostomy should be considered. Cutaneous pyelostomy rarely affords better drainage when compared with cutaneous vesicostomy, and the latter also allows continued bladder growth and gradual improvement in bladder wall compliance.

In the septic and uremic infant, lifesaving measures must include prompt correction of the electrolyte imbalance and control of the infection by appropriate antibiotics. Drainage of the upper tracts by percutaneous nephrostomy and hemodialysis may be necessary. In newborn boys with posterior urethral valves have unilateral reflux into a nonfunctioning dysplastic kidney, termed the VURD syndrome (valves, unilateral reflux, dysplasia). In these boys, the high bladder pressure is dissipated into the nonfunctioning kidney, allowing normal development of the contralateral kidney. In newborn boys with urinary ascites, the urine generally leaks out from the obstructed collecting system through the renal fornices, allowing normal development of the kidneys. Unfavorable prognostic factors include the presence of oligohydramnios in utero, identification of hydronephrosis before 24 wk of gestation, a serum creatinine level >1.0 mg/dL after bladder decompression, identification of cortical cysts in both kidneys, and persistence of diurnal incontinence beyond 5 yr of age.

Figure 540-10 Neonate with primary nonrefluxing megaureter. A, Renal sonogram shows grade 4 hydronephrosis. B, Dilated ureter. Renal scan showed equal function with the contralateral kidney and satisfactory drainage with diuresis stimulation. C, Follow-up sonogram at 10 mo shows complete resolution of hydronephrosis.

Figure 540-11 Photograph of a 1,600-g newborn with the prune-belly syndrome. Note the lack of tonicity of the abdominal wall and the wrinkled appearance of the skin.

Figure 540-12 Voiding cystourethrogram in an infant with posterior urethral valves. Note the dilation of the prostatic urethra and the transverse linear filling defect corresponding to the valves.
The prognosis in the newborn is related to the child’s degree of pulmonary hypoplasia and potential for recovery of renal function. Severely affected infants often are stillborn. Of those who survive the neonatal period, approximately 30% eventually require kidney transplantation and 15% have renal insufficiency. In some series, kidney transplantation in children with posterior urethral valves has a lower success rate than does transplantation in children with normal bladders, presumably because of the adverse influence of altered bladder function on graft function and survival.

After valve ablation, antimicrobial prophylaxis is beneficial in preventing UTI, because hydropnephrosis to some degree often persists for many years. These boys should be evaluated annually with a renal ultrasonogram, physical examination including assessment of somatic growth and blood pressure, urinalysis, and determination of serum levels of electrolytes. Many boys have significant polyuria resulting from a concentrating defect secondary to prolonged obstructive uropathy. If these children acquire a systemic illness with vomiting and/or diarrhea, urine output cannot be used to assess their hydration status. They can become dehydrated quickly, and there should be a low threshold for hospital admission for intravenous rehydration. Some of these patients have renal tubular acidosis, requiring oral bicarbonate therapy. If there is any significant degree of renal dysfunction, growth impairment, or hypertension, the child should be followed closely by a pediatric nephrologist. When vesicoureteral reflux is present, expectant treatment and prophylactic doses of antibacterial drugs are advisable. If breakthrough UTI occurs, surgical correction should be undertaken.

After treatment, boys with urethral valves often do not achieve diurnal urinary continence as early as other boys. Incontinence can result from a combination of factors, including uninhibited bladder contractions, poor bladder compliance, bladder atonia, bladder neck dyssynergia, or polyuria. Often these boys require urodynamic evaluation with urodynamics or videourodynamics to plan therapy. Boys with noncompliance are at significant risk for ongoing renal damage, even in the absence of infection. Overnight catheter drainage has been shown to be beneficial in boys with polyuria and can help preserve renal function. Urinary incontinence usually improves with age, particularly after puberty. Meticulous attention to bladder compliance, emptying, and infection can improve results in the future.

Urethral Atresia
The most severe form of obstructive uropathy in boys is urethral atresia, a rare condition. In utero there is a distended bladder, bilateral hydroureteronephrosis, and oligohydramnios. In most cases, these infants are stillborn or succumb to pulmonary hypoplasia. Some boys with prune-belly syndrome also have urethral atresia. If the urachus is patent, oligohydramnios is unlikely and the infant usually survives. Urethral reconstruction is difficult, and most patients are managed with continent urinary diversion.

Urethral Hypoplasia
Urethral hypoplasia is a rare form of obstructive uropathy in boys that is less severe than urethral atresia. In urethral hypoplasia, the urethral lumen is extremely small. Neonates with urethral hypoplasia typically have bilateral hydroureteronephrosis and a distended bladder. Passage of a small pediatric feeding tube through the urethra is difficult or impossible. Usually a cutaneous vesicostomy must be performed to relieve upper urinary tract obstruction, and the severity of renal insufficiency is variable. The most severely affected boys have end-stage renal disease. Treatment includes urethral reconstruction, gradual urethral dilation, or continent urinary diversion.

Urethral Strictures
Urethral strictures in boys usually result from urethral trauma, either iatrogenic (catheterization, endoscopic procedures, previous urethral reconstruction) or accidental (straddle injuries, pelvic fractures). Because these lesions can develop gradually, the decrease in force of the urinary stream is seldom noticed by the child or the parents. More commonly, the obstruction causes symptoms of bladder instability, hematuria, or dysuria. Catheterization of the bladder usually is impossible. The diagnosis is made by a retrograde urethrogram, in which contrast is injected toward the bladder through a catheter inserted into the distal urethra. Ultrasonography also has been used to diagnose urethral strictures. Endoscopy is confirmatory. Endoscopic treatment of short strictures by direct vision urethrotomy is often successful initially and results in a profoundly improved urinary stream, but often the stricture recurs and is found at long-term follow-up. Longer strictures surrounded by periurethral fibrosis often require urethroplasty. Repeated endoscopic procedures generally should be avoided, because they can cause additional urethral damage. Noninvasive measurement of the urinary flow rate and pattern is useful for diagnosis and follow-up.

In girls, true urethral strictures are rare because the female urethra is protected from trauma, particularly in childhood. In the past it was thought that a distal urethral ring commonly caused obstruction of the female urethra and UTI and that affected girls benefited from urethral dilation. The diagnosis was suspected when a “spinning top” deformity of the urethra was found in the VCU (see Fig. 543-3 in Chapter 543) and was confirmed by urethral calibration. There is no correlation between the radiologic appearance of the urethra in the VCU and the urethral caliber and no significant difference in urethral caliber between girls with recurrent cystitis and normal age-matched controls. The finding usually is secondary to detrusor–sphincter dyssynergia. Consequently, urethral dilation in girls rarely is indicated.

Anterior Urethral Valves and Urethral Diverticula in the Male
Anterior urethral valves are rare. The obstruction is not obstructing valve leaflets, as occurs in the posterior urethra. Rather, it is a urethral diverticulum in the penile urethra that expands during voiding. Distal extension of the diverticulum causes extrinsic compression of the distal penile urethra, causing urethral obstruction. Typically there is a soft mass on the ventral surface of the penis at the penoscrotal junction. In addition, the urinary stream often is weak, and the physical findings associated with posterior urethral valves are absent. The diverticulum may be small and minimally obstructive, or, in other cases, may be severely obstructive and cause renal insufficiency. The diagnosis is suspected on physical examination and is confirmed by the VCUG. Treatment involves open excision of the diverticulum or transurethral excision of the distal urethral cusp. Urethral diverticulosis occasionally occurs after extensive hypospadias repair. Fusiform dilation of the urethra or megalourethra can result from underdevelopment of the corpus spongiosum and support structures of the urethra. This condition is commonly associated with the prune-belly syndrome.

Male Urethral Meatal Stenosis
See Chapter 544 for information on urethral meatal stenosis in males.

BLADDER EXSTROPHY

Extrophy of the urinary bladder occurs in approximately 1 in 35,000-40,000 births. The male:female ratio is 2:1. The severity ranges from simple epispadias (in boys) to complete extrophy of the cloaca involving exposure of the entire hindgut and the bladder (termed cloacal extrophy).
Clinical Manifestations

Anomalies of the bladder are hypothesized to result when the mesoderm fails to invaginate the cephalad extension of the cloacal membrane; the extent of this failure determines the degree of the anomaly. In classic bladder exstrophy (Fig. 541-1), the bladder protrudes from the abdominal wall and its mucosa is exposed. The umbilicus is displaced downward, the pubic rami are widely separated in the midline, and the rectus muscles are separated. In boys, there is complete epispadias with dorsal chordee, and the overall penile length is approximately half that of unaffected boys. The scrotum typically is separated slightly from the penis and is wide and shallow. Undescended testes and inguinal hernias are common. Girls also have epispadias, with separation of the 2 halves of the clitoris and wide separation of the labia. The anus is displaced anteriorly in both sexes, and there may be rectal prolapse. The pubic rami are widely separated. Persons with exstrophy tend to be shorter than normal.

The consequences of untreated bladder exstrophy are total urinary incontinence and an increased incidence of bladder cancer, usually adenocarcinoma. The genital deformities can produce sexual disability in both sexes, particularly in males. The wide separation of the pubic rami causes a characteristic broad-based gait but no significant disability. In classic bladder exstrophy, the upper urinary tracts usually are normal.

Treatment

Management of bladder exstrophy should start at birth. The bladder should be covered with plastic wrap to keep the bladder mucosa moist. Application of gauze or petroleum-gauze to the bladder mucosa should be avoided, because significant inflammation will result. The infant should be transferred promptly to a center with pediatric urologic and anesthetic support for the treatment of such anomalies. These children are prone to latex allergy, so latex precautions should be practiced in their care.

There are 2 surgical approaches: staged reconstruction and total single-stage reconstruction. Most babies also undergo bilateral iliac osteotomy, which allows the pubic symphysis to be approximated, which supports the bladder closure. In a staged reconstruction, the initial stage is bladder closure, the 2nd stage (in boys) is epispadias repair, and the final stage is bladder neck reconstruction. The single-stage reconstruction attempts to reconstruct the entire malformation in a single procedure. When this operation is performed in the newborn, there is an increased risk of intraoperative penile injury and postoperative hydronephrosis, compared with the staged reconstruction. The complication rate is high with both approaches and there is no consensus on which is better.

Although bladder closure within 48 hr has been the standard in the past, more recently, many centers of excellence defer the procedure for 1-2 wk to be certain that the appropriate experienced surgical and anesthetic team is available. During bladder exstrophy closure, the abdominal wall is mobilized and the pubic rami are brought together in the midline following pelvic osteotomy. Early bladder closure can be performed in almost all neonates with classic bladder exstrophy. Treatment should be deferred in selected situations when surgical therapy would be excessively risky or complex, such as in a premature baby or when it would have to be performed by inexperienced surgeons. In the staged approach, in boys, epispadias repair usually is performed at 1-2 yr of age. At this point the child has total urinary incontinence because there is no functional external urinary sphincter.

At 3-6 yr, if the bladder is sufficiently large, bladder neck reconstruction is performed to try to create a functional sphincter.

Total single-stage reconstruction includes closure of the bladder, closure of the abdominal wall, and, in boys, correction of epispadias using a technique of penile disassembly, in which the 2 corpora cavernosa and the midline urethra are mobilized separately into 3 parts. Postoperatively, the infant's upper urinary tract is monitored closely for the possible development of hydronephrosis and infection. Most infants with bladder exstrophy have vesicoureteral reflux and should receive antibiotic prophylaxis. The final stage of reconstruction involves creation of a sphincter muscle for bladder control and correction of the vesicoureteral reflux. At this point the child is 3-6 yr old, the bladder capacity should be at least 80-90 mL, and the child must have gained rectal control. Typically, bladder capacity is monitored every 12-24 mo using cystoscopy under anesthesia.

At puberty, often the pubic hair is distributed to the sides of the external genitals. A monsplasty can performed to provide a normal escutcheon.

Long-Term Prognosis

This plan of treatment has yielded a continence rate of 60-70% in a few centers, with <15% deterioration of the upper urinary tract. This continence rate reflects not only the successful reconstruction but also the quality and size of the bladder. The reconstructed bladder neck does not relax during voiding as in a normal child; instead the patient must void by Valsalva. Children who undergo reconstructive surgery as newborns have a greater chance of obtaining a normally functioning bladder.

Children who remain incontinent for more than 1 yr after bladder neck reconstruction or those who are not eligible for bladder neck reconstruction because of a small bladder capacity are candidates for an alternative reconstructive procedure to achieve dryness. In selected cases, cystoscopic injection of dextranomer or polydimethylsiloxane microspheres into the bladder neck can provide sufficient bladder neck coaptation to establish continence. Alternatively, if the child is not a candidate for endoscopic therapy, options include:

- Augmentation cystoplasty, in which the bladder is enlarged with a patch of small or large bowel to increase its capacity.
- Creation of a neobladder out of small and large bowel with placement of a continent abdominal stoma through which clean intermittent catheterization can be performed.
- Placement of an artificial urinary sphincter, with possible augmentation cystoplasty.
- Ureterosigmoidostomy, in which the ureters are detached from the bladder and sutured to the sigmoid colon; individuals void urine and stool from the rectum and rely on their anal sphincter for continence.
- Mainz II procedure, in which the sigmoid colon is reconfigured into a “bladder” into which the ureters are connected, and the patient voids 3-6 times daily through the rectum, and the stool tends to be more solid.

Ureterosigmoidostomy carries a significant risk of chronic pyelonephritis (see Chapter 538), upper urinary tract damage, metabolic acidosis resulting from absorption of hydrogen ion and chloride in the intestine, and at least a 15% long-term risk of colon carcinoma. Patients from less-developed countries often undergo the Mainz II procedure because the continence rate is high and pyelonephritis and upper tract changes are uncommon.
Late follow-up has shown that although men with exstrophy have a penis that is half normal length, they usually experience satisfactory sexual function. Fertility has been low, possibly because of iatrogenic injury to the secondary sexual organs during reconstruction. With artificial re reproductive technology, nearly all men can be fertile. In women, fertility is not affected, but uterine prolapse during pregnancy is a problem. In women who have undergone a continent urinary diversion, delivery by cesarean section may be necessary.

OTHER EXSTROPHY ANOMALIES
Children with more complex cases of cloacal exstrophy, which has an incidence of 1 in 400,000, have an omphalocele and severe abnormalities of the colon and the rectum and often have short bowel syndrome (see Chapter 338.7), the most devastating anomaly managed by pediatric urologists. Approximately 50% of patients have an upper urinary tract anomaly, and 50% have spina bifida (see Chapter 591). Children with cloacal exstrophy do not achieve normal urine or stool continence. Reconstructive techniques result in a satisfactory outcome in most patients with permanent urinary diversion (either ileal conduit or continent urinary diversion) and a colostomy. Because the penis in boys with cloacal exstrophy usually is diminutive, genital reconstruction in boys with cloacal exstrophy has been unsatisfactory. Until recently, most specialists recommended assigning a female gender to such infants, but currently there is debate whether these children, who have a 46,XY karyotype and androgen imprinting in utero, can have a satisfactory female gender identity (see Chapter 110.2). Many assume male gender characteristics by adolescence. Decisions regarding gender assignment should be made jointly by the physicians caring for the infant (surgical team, pediatric endocrinologist, child psychiatrist, and ethicist) and family.

Epispadias is in the spectrum of exstrophy anomalies, affecting approximately 1 in 117,000 boys and 1 in 480,000 girls. In boys, the diagnosis is obvious because the prepuce is distributed primarily on the ventral aspect of the penis shaft and the urethral meatus is on the dorsum of the penis. Distal epispadias in boys usually is associated with normal urinary control and normal upper urinary tracts and should be repaired by 6-12 mo of age. In girls, the clitoris is bifid and the urethra is split dorsally (Fig. 541-2). In more severely affected boys and in all girls with epispadias, there is total urinary incontinence because the sphincter is incompletely formed, and there is wide separation of the pubic rami. These children require surgical reconstruction of the bladder neck, similar to the final management stage in children with classic bladder exstrophy.

BLADDER DIVERTICULA
Bladder diverticula develop as herniations of bladder mucosa between defects of bladder smooth muscle fibers. Primary bladder diverticula usually develop at the ureterovesical junction and may be associated with vesicoureteral reflux, because the diverticulum interferes with the normal flap-valve attachment between the ureter and bladder. In rare circumstances the diverticulum is so large that it interferes with normal micturition by obstructing the bladder neck. Bladder diverticula also commonly are associated with distal urethral obstruction such as posterior urethral valves or neurogenic bladder dysfunction. They occur commonly in children with connective tissue disorders including Williams syndrome, Ehlers-Danlos syndrome, and Menkes syndrome (Fig. 541-3). Small diverticula require no treatment other than that of the primary disease, whereas large diverticula can contribute to inefficient voiding, residual urine, urinary stasis, and urinary tract infections and should be excised.

URACHAL ANOMALIES
The urachus is an embryologic canal connecting the dome of the fetal bladder with the allantois, a structure that contributes to the formation of the umbilical cord. The lumen of the urachus is normally obliterated during embryonic development, transforming the urachus into a solid cord. Urachal abnormalities are more common in boys than in girls. A patent urachus can occur as an isolated anomaly; it may be associated with prune-belly syndrome or posterior urethral valves (see Chapter 540). In this condition there is continuous urinary drainage from the umbilicus. The tract should be excised. Another urachal anomaly is the urachal cyst, which can become infected. Typical symptoms and physical findings include suprapubic pain, fever, irritative voiding symptoms, and an infraumbilical mass, which can be erythematous. Diagnosis is made by ultrasonography or CT (Fig. 541-4).
Treatment is intravenous antibiotic therapy and drainage and excision. Other urachal anomalies include the vesicourachal diverticulum, which is a diverticulum of the bladder dome, and umbilical–urachal sinus, which is a blind external sinus that opens at the umbilicus. These lesions should be excised.

Chapter 541  Anomalies of the Bladder 2578.e1

Bibliography
Neuropathic bladder dysfunction in children usually is congenital, generally resulting from neural tube defects or other spinal abnormalities. Acquired diseases and traumatic lesions of the spinal cord are less common. Central nervous system tumors, sacrococcygeal teratoma, spinal abnormalities associated with imperforate anus (see Chapter 344), and spinal cord trauma also can result in abnormal innervation of the bladder and/or sphincter.

**NEURAL TUBE DEFECTS**

Neural tube defects, resulting from failure of the neural tube to close spontaneously between the 3rd and 4th wk in utero, result in abnormalities of the vertebral column that affect spinal cord function, including myelomeningocele and meningocele (see Chapter 591). A few medical centers in the United States have been performing antenatal myelomeningocele closure. Long-term results from one large trial (the “MOMS trial”), have not shown a definite improvement in lower urinary tract function, although some children have demonstrated nearly normal bladder function, and overall there has been a significant reduction in the need for ventriculoperitoneal shunting.

**CLINICAL MANIFESTATIONS AND DIAGNOSIS**

The most important urologic consequences of neuropathic bladder dysfunction associated with neural tube defects are urinary incontinence (see Chapter 543), urinary tract infections (UTIs; see Chapter 538), and hydronephrosis from vesicoureteral reflux (see Chapter 539), or detrusor–sphincter dyssynergia (see Chapter 540). Pyelonephritis and renal functional deterioration (see Chapter 535) are common causes of premature death of affected patients.

In the neonate, renal ultrasonography, assessment of postvoid residual urine volumes, and a voiding cystourethrogram are performed after closure of the myelomeningocele. Approximately 10-15% of newborns with myelomeningocele have hydronephrosis, and renal malformations are common; 25% have vesicoureteral reflux. A urodynamic study also should be performed. This study involves filling the bladder with saline, measuring the bladder volume and pressure, and assessing sphincter tone. During bladder filling, the bladder might show (1) uninhibited (premature) contractions (termed hyperreflexia) at low volumes, (2) normal bladder volume with contraction at an appropriate volume, or (3) atonia (lack of bladder contraction). Bladder compliance or elasticity also may be reduced. The sphincter can show (1) normal tonic with relaxation during bladder contraction, (2) reduced or absent tonic, or (3) normal or increased tonic that increases during a bladder contraction (termed detrusor-sphincter dyssynergia) (Fig. 542-1).

**RENAL DAMAGE**

Renal damage usually results from detrusor–sphincter dyssynergia. This dyssynergia causes functional obstruction of the bladder outlet, leading to bladder muscle hypertrophy and trabeculation, high intravesical pressure, and transmission of this high pressure into the upper urinary tracts, causing hydronephrosis (Fig. 542-2). Vesicoureteral reflux and UTI compound the problem. Treatment includes reduction of bladder pressure with anticholinergic drugs (e.g., oxybutynin, 0.2 mg/kg/24 hr in 2 or 3 divided doses) and clean intermittent catheterization every 3-4 hr. If the child has vesicoureteral reflux or UTI, antimicrobial prophylaxis also is prescribed.

Temporary urinary diversion by cutaneous vesicostomy is an alternative in the newborn or infant with severe reflux, if intermittent catheterization is difficult or anticholinergic medications are not well tolerated. Another option to treat the severely trabeculated bladder is transurethral injection of botulinum toxin (Botox) into the detrusor muscle, which reduces bladder hypertonicity for approximately 6 mo. A different approach in these children is to temporarily inactivate the tight sphincter by urethral overdilation or transurethral injection of botulinum toxin into the sphincter. In children with upper tract changes, continuous overnight bladder drainage allows significant bladder relaxation and can reduce bladder wall thickening and lessen hydronephrosis.

Clean intermittent catheterization and anticholinergic therapy cure reflux in up to 80% of children with grade I or II reflux. Children with more severe reflux often require subureteral endoscopic injection therapy (see Chapter 539) or open antireflux surgery followed by intermittent catheterization and anticholinergic drugs. In older children with myelomeningocele with high-grade reflux, UTI, and hydronephrosis, augmentation enterocystoplasty (enlarging the bladder with a
Incontinence in the child with neuropathic bladder can result from total or partial denervation of the sphincter, bladder hyperreflexia, poor bladder compliance, chronic urinary retention, or a combination of these factors.

Incontinence often is addressed around 4 yr of age and is tailored to the individual child. Nearly all children require clean intermittent catheterization to stay dry. This technique allows efficient bladder emptying with minimal risk of symptomatic UTI. The urinary tract should be reevaluated with renal ultrasonography, a voiding cystourethrogram, and a urodynamic study, including bladder capacity. If the external sphincter tone is sufficient and the bladder has adequate compliance, intermittent catheterization every 3–4 hr usually is successful in keeping the child dry. If there are unstable bladder contractions, an anticholinergic medication such as oxybutynin chloride, hyoscyamine, or toterodine is prescribed to increase bladder capacity. If there is sphincter incompetence, α-adrenergic medications are prescribed to enhance outlet resistance. Bacteriuria is seen in up to 50% of children using intermittent self-catheterization, but it seldom causes symptoms. In the absence of reflux, there seems to be little cause for concern. Performing intermittent catheterization with a new catheter (hydrophilic or standard silicone) each time also is quite effective in preventing bacteriuria and avoids the need for antibiotic prophylaxis. With this treatment plan, 40–85% of patients are dry, depending on the definition of continence; some children wear a pad in their underwear or a diaper but feel that they are dry.

If there is persistent incontinence despite medical therapy, reconstructive urinary tract surgery nearly always can provide complete or satisfactory continence. If urethral resistance is low, bladder neck reconstructive procedures such as a periurethral sling often are successful. Alternatively, implantation of an artificial sphincter usually is successful. This sphincter consists of an inflatable cuff that is placed around the bladder neck, a pressure-regulating balloon implanted in the extraperitoneal space, and a pumping mechanism that is implanted in the scrotum of boys and in the labia majora of girls. If the bladder capacity or bladder compliance is low, or if there are persistent uninhibited contractions despite anticholinergic therapy, enlargement of the bladder with a patch of small or large intestine, termed augmenta-

tion cystoplasty or enteroctystoplasty, is effective.

These patients still need to perform clean intermittent catheterization. If urethral catheterization is difficult, a continent urinary stoma may be incorporated into the urinary tract reconstruction. A common method is the Mitrofanoff procedure, in which the appendix is isolated from the cecum on its vascular pedicle and is interposed between the bladder and abdominal wall to allow intermittent catheterization through a dry stoma. An ileal conduit with a bag on the abdominal wall is rarely used.

Complications of Augmentation Cystoplasty

Urinary Tract Infection

The urine may be colonized with Gram-negative bacteria, and attempts to sterilize the urine for prolonged periods usually fail. There is no evidence that chronic bacteriuria in patients who have had enterocystoplasty is associated with renal damage; therefore, only symptomatic UTIs should be treated.

Metabolic Acidosis

The enteric mucosal surface in contact with the urine absorbs ammonium, chloride, and hydrogen ions and loses potassium. Hyperchloremic metabolic acidosis can result, possibly requiring medical treatment (see Chapter 55). Chronic acidosis can compromise skeletal growth. This condition is common with colocolystoplasty but is rare with ileocolystoplasty. Metabolic acidosis also is common in patients with compromised renal function. To overcome this limitation of enteroctystoplasty in patients with chronic renal insufficiency, a composite augmentation using stomach and small or large bowel gastric segment can be used. The stomach secretes chloride and hydrogen ions; thus, preexisting metabolic acidosis remains stable or improves.

Spontaneous Perforation

Perforation of the augmented bladder is a life-threatening complication that results most often from acute or chronic overdistention of the augmented bladder. Patients with this complication typically present with severe abdominal pain and signs of peritonitis. Prompt diagnosis and treatment with exploratory laparotomy and bladder closure are necessary. Meticulous adherence to the prescribed program of intermittent catheterization to avoid bladder overdistention is important.

Bladder Calculi

Bladder calculi have developed in as many as 70% of children followed for 10 yr after enterocystoplasty. The calculi develop in response to bladder overdistention that results most often from acute or chronic overdistention of the augmented bladder. Patients with this complication typically present with severe abdominal pain and signs of peritonitis. Prompt diagnosis and treatment with exploratory laparotomy and bladder closure are necessary. Meticulous adherence to the prescribed program of intermittent catheterization to avoid bladder overdistention is important.

Malignant Neoplasm

Invasive transitional cell carcinoma has been reported in nearly 2% of patients undergoing enterocystoplasty (compared with a 1% risk in spina bifida patients without enterocystoplasty). The pathogenesis is uncertain but is speculated that it is related to bacteriuria and the bowel-bladder contact. The risk seems to be highest following gastrocystoplasty. The risk seems to increase 10 yr following enterocystoplasty. Although these patients probably should undergo screening, there are no guidelines or recommendations regarding this practice. It seems appropriate to advise yearly endoscopic examinations or urine cytologic studies beginning in the 10th postoperative year.

Future Management

The development of a tissue-engineered bladder using a composite scaffold, which could be attached to the dome of the bladder to increase capacity and compliance, might help patients achieve continence.
In addition, there is a nerve-rerouting procedure in which the dorsal nerve root from the lumbar nerve is sutured to the ventral sacral nerve root, allowing the child to scratch the thigh to stimulate a bladder contraction. This procedure is controversial.

**ASSOCIATED DISORDERS**

**Constipation**

Many patients with spina bifida also have bowel problems with constipation, and a vigorous bowel regimen is important. Some benefit from the **Malone antegrade continence enema procedure**, in which the appendix is brought out to the skin to allow a catheter to be inserted into the cecum for antegrade enema. The stoma is continent, and an antegrade enema can be performed with tap water each day. This form of management allows the patient to be continent of stool and be more self-sufficient.

**Latex Allergy**

Latex allergy is a very serious problem encountered by as many as half of patients with spina bifida and other urologic conditions who require clean intermittent catheterization and urinary tract reconstructive procedures. This immunoglobulin E–mediated allergy is acquired and is secondary to repeated exposure to the latex allergen. Latex allergy can manifest as watery eyes, sneezing, itching, hives, or anaphylaxis when blowing up a balloon or if an examiner is using latex gloves. Intraoperatively, a sensitized patient can experience anaphylactic shock. A latex-free environment should be provided for all children with spina bifida in the office, during hospitalization, and during operative procedures. Affected children also should wear a medical alert bracelet.

**Occult Spinal Dysraphism**

Approximately 1 in 4,000 patients have occult spinal dysraphism, a category that includes lipomeningocele, intradural lipoma, diastematomyelia, tight filum terminale, dermoid cyst-sinus, aberrant nerve roots, anterior sacral meningocele, and cauda equina tumor. More than 90% of patients have a cutaneous abnormality overlying the lower spine, including a small dimple, tuft of hair, dermal vascular malformation, or subcutaneous lipoma (Fig. 542-4). Often these children have high-arched feet, discrepancy in muscle size and strength between the legs, and a gait abnormality. Newborns and young infants often have a normal neurologic examination. Older children often have absent perineal sensation and back pain. Lower urinary tract function is abnormal in 40% of patients, including incontinence, recurrent UTI, and fecal soiling. The likelihood of a normal examination is inversely related to the child's age at surgical correction of the spinal lesion. In infants with abnormal urodynamics, 60% revert to normal; in older children, only 27% become normal. Management of the urinary tract in other children is similar to that described earlier for neural tube defects.

**Sacral Agenesis**

Sacral agenesis is defined as the absence of part or all of ≥2 lower vertebral bodies. This condition is more common in the offspring of women with diabetes. These children have a flattened buttock and a low, short gluteal cleft but usually have no orthopedic deformity, although some have high-arched feet. Palpation of the coccygeal area detects the absent vertebrae. Approximately 20% of cases are undetected until the age of 3-4 yr; many are diagnosed after unsuccessful
toilet training. Urodynamic studies in these children show a variety of patterns, and most need clean intermittent catheterization and pharmacotherapy to stay dry.

**Imperforate Anus**
Approximately 30-45% of children with a high imperforate anus have a neuropathic bladder, often because of sacral agenesis. Newborns with imperforate anus should undergo a spinal ultrasound during their initial evaluation, and if these children have difficulty with toilet training, complete urologic evaluation with upper and lower urinary tract imaging and urodynamics should be performed. See Chapter 344 for further details.

**Cerebral Palsy**
Children with cerebral palsy (see Chapter 598.1) often have reasonable bladder control. However, they achieve continence at a later age than unaffected children. Overall, 25-50% are incontinent, and the risk is directly related to the severity of physical impairment. Their upper urinary tracts usually are normal. Urodynamic studies have shown that most have uninhibited bladder contractions. Timed voiding and anticholinergic therapy are usually effective. Clean intermittent catheterization rarely is necessary.

Causes of Urinary Incontinence

DIURNAL INCONTINENCE was dysfunctional elimination syndrome. The previous term for this condition was coined by the American Urological Association Vesico-intestinal disorders that do not have underlying structural or tissue-based causes. Children 4 yr of age or older are diagnosed as being incontinence is an overactive bladder (urge incontinence). At age 5 yr, 95% have been dry during the day at some time and 92% are dry. At 7 yr, 96% are dry, although 15% have significant urgency at times. At 12 yr, 99% are dry during the day. Table 543-1 lists the causes of diurnal incontinence in children.

The history should assess the pattern of incontinence, including the frequency, the volume of urine lost during incontinent episodes, whether the incontinence is associated with urgency or giggling, whether it occurs after voiding, and whether the incontinence is continuous. The frequency of voiding and whether there is nocturnal enuresis, a strong, continuous urinary stream, or sensation of incomplete bladder emptying should be assessed. A diary of when the child voids and whether the child was wet or dry is helpful. Other urologic problems such as urinary tract infections (UTIs), vesicoureteral reflux, neurologic disorders, or a family history of duplication anomalies should be assessed. Bowel habits also should be evaluated, because incontinence is common in children with constipation and/or encopresis. Diurnal incontinence can occur in girls with a history of sexual abuse. Physical examination is directed at identifying signs of organic causes of incontinence: short stature, hypertension, enlarged kidneys and/or bladder, constipation, labial adhesion, ureteral ectopy, back or sacral anomalies (see Fig. 542-4 in Chapter 542), and neurologic abnormalities.

Assessment tools include urinalysis, with culture if indicated; bladder diary (recorded times and volumes voided, whether wet or dry); postvoid residual urine volume (generally obtained by bladder scan); and Dysfunctional Voiding Symptom Score (Fig. 543-1). An alternative to the Dysfunctional Voiding Symptom Score is the Vancouver Nonneurogenic Lower Urinary Tract Dysfunction/Dysfunctional Elimination Syndrome questionnaire. This questionnaire is a validated tool that consists of 14 questions scored on a 5-point Likert scale to assess lower urinary tract and bowel dysfunction. In most cases, a uroflow with or without electromyography (noninvasive assessment of urinary flow pattern and measurement of external sphincter activity) is indicated. Another item that may be useful in children older than age 5 yr is the Pediatric Symptom Checklist (PSC). The Pediatric Symptom Checklist is a brief screening questionnaire consisting of 35 questions that is used by pediatricians and other health professionals to improve the recognition and treatment of psychosocial problems in children.

Bowel function should be assessed also. The Bristol Stool Form Score (Fig. 543-2) also should be recorded. In addition, the clinician should utilize the Rome III diagnostic criteria, which classify functional gastrointestinal disorders that do not have underlying structural or tissue-based causes. Children 4 yr of age or older are diagnosed as being

NORMAL VOIDING AND TOILET TRAINING
Fetal voiding occurs by reflex bladder contraction in concert with simultaneous contraction of the bladder and relaxation of the sphincter. Urine storage results from sympathetic and pudendal nerve-mediated inhibition of detrusor contractile activity accompanied by closure of the bladder neck and proximal urethra with increased activity of the external sphincter. The infant has coordinated reflex voiding as often as 15-20 times/day. Over time, bladder capacity increases. In children up to the age of 14 yr, the mean bladder capacity in ounces is equal to the age (in years) plus 2.

At 2-4 yr, the child is developmentally ready to begin toilet training. To achieve conscious bladder control, several conditions must be present: awareness of bladder filling; cortical inhibition (suprapontine modulation) of reflex (unstable) bladder contractions; ability to consciously tighten the external sphincter to prevent incontinence; normal bladder growth; and motivation by the child to stay dry. The transitional phase of voiding refers to the period when children are acquiring bladder control. Girls typically acquire bladder control before boys, and bowel control typically is achieved before bladder control.

A common condition in children is bladder–bowel dysfunction. This term was coined by the American Urological Association Vesico-ureteral Reflux Guidelines Committee and refers to disorders of bladder and/or bowel function. The previous term for this condition was dysfunctional elimination syndrome.

DIURNAL INCONTINENCE
Daytime incontinence not secondary to neurologic abnormalities is common in children. The most common cause of daytime incontinence is an overactive bladder (urge incontinence). At age 5 yr, 95% have been dry during the day at some time and 92% are dry. At 7 yr, 96% are dry, although 15% have significant urgency at times. At 12 yr, 99% are dry during the day. Table 543-1 lists the causes of diurnal incontinence in children.

The history should assess the pattern of incontinence, including the frequency, the volume of urine lost during incontinent episodes, whether the incontinence is associated with urgency or giggling, whether it occurs after voiding, and whether the incontinence is continuous. The frequency of voiding and whether there is nocturnal enuresis, a strong, continuous urinary stream, or sensation of incomplete bladder emptying should be assessed. A diary of when the child voids and whether the child was wet or dry is helpful. Other urologic problems such as urinary tract infections (UTIs), vesicoureteral reflux, neurologic disorders, or a family history of duplication anomalies should be assessed. Bowel habits also should be evaluated, because incontinence is common in children with constipation and/or encopresis. Diurnal incontinence can occur in girls with a history of sexual abuse. Physical examination is directed at identifying signs of organic causes of incontinence: short stature, hypertension, enlarged kidneys and/or bladder, constipation, labial adhesion, ureteral ectopy, back or sacral anomalies (see Fig. 542-4 in Chapter 542), and neurologic abnormalities.

Assessment tools include urinalysis, with culture if indicated; bladder diary (recorded times and volumes voided, whether wet or dry); postvoid residual urine volume (generally obtained by bladder scan); and Dysfunctional Voiding Symptom Score (Fig. 543-1). An alternative to the Dysfunctional Voiding Symptom Score is the Vancouver Nonneurogenic Lower Urinary Tract Dysfunction/Dysfunctional Elimination Syndrome questionnaire. This questionnaire is a validated tool that consists of 14 questions scored on a 5-point Likert scale to assess lower urinary tract and bowel dysfunction. In most cases, a uroflow with or without electromyography (noninvasive assessment of urinary flow pattern and measurement of external sphincter activity) is indicated. Another item that may be useful in children older than age 5 yr is the Pediatric Symptom Checklist (PSC). The Pediatric Symptom Checklist is a brief screening questionnaire consisting of 35 questions that is used by pediatricians and other health professionals to improve the recognition and treatment of psychosocial problems in children.

Bowel function should be assessed also. The Bristol Stool Form Score (Fig. 543-2) also should be recorded. In addition, the clinician should utilize the Rome III diagnostic criteria, which classify functional gastrointestinal disorders that do not have underlying structural or tissue-based causes. Children 4 yr of age or older are diagnosed as being
constipated if they fulfill 2 or more of the following criteria over a period of 2 mo: 2 or fewer defecations in the toilet per week, at least 1 episode of fecal incontinence per week, a history of retentive posturing or excessive volitional stool retention, history of painful or hard bowel movements, presence of a large fecal mass in the rectum, and history of large-diameter stools that obstruct the toilet.

Imaging is performed in children who have significant physical findings, a family history of urinary tract anomalies or UTIs, and those who do not respond to therapy appropriately. A renal ultrasonogram with or without a voiding cystourethrogram is indicated. Urodynamics should be performed if there is evidence of neurologic disease and may be helpful if empirical therapy is ineffective. If there is any evidence of a neurologic disorder, an MRI of the lower spine should be obtained.

OVERACTIVE BLADDER (DIURNAL URGE SYNDROME)

Children with an overactive bladder typically exhibit urinary frequency, urgency, and urge incontinence. Often a girl will squat down on her foot to try to prevent incontinence (termed Vincent’s curtsy). The bladder in these children is functionally, but not anatomically, smaller than normal and exhibits strong uninhibited contractions. Approximately 25% of children with nocturnal enuresis also have symptoms of an overactive bladder. Many children indicate they do not feel the need to urinate, even just before they are incontinent. In girls, a history of recurrent UTI is common, but incontinence can persist long after infections are brought under control. It is not clear if the voiding dysfunction is a sequela of the UTIs or if the voiding dysfunction predisposes to recurrent UTIs. In girls, voiding cystourethrogram often shows a dilated urethra (“spinning-top deformity,” Fig. 543-3) and narrowed bladder neck with bladder wall hypertrophy. The urethral finding results from inadequate relaxation of the external

**Figure 543-2** Bristol Stool Chart for evaluating bowel function.
The overactive bladder nearly always resolves, but the time to resolution is highly variable, sometimes not until the teenage years. Initial therapy is timed voiding, every 1.5-2.0 hr. Treatment of constipation and UTIs is important. Another treatment is biofeedback, in which children are taught pelvic floor exercises (Kegel exercises), because there is evidence that daily performance of these exercises can reduce or eliminate unstable bladder contractions. Biofeedback often includes participation with animated computer games. Biofeedback also may include periodic uroflow studies with sphincter electromyography to be certain that the pelvic floor relaxes during voiding, and assessment of postvoid residual urine volume by sonography. Anticholinergic therapy with oxybutynin chloride, hyoscycamine, or tolterodine reduces bladder overactivity and may help the child achieve dryness. Treatment with an α-adrenergic blocker such as terazosin or doxazosin can aid in bladder emptying by promoting bladder neck relaxation; α-adrenergic blockers also have mild anticholinergic properties. If pharmacologic therapy is successful, the dosage should be tapered periodically to determine its continued need. Children who do not respond to therapy should be evaluated urodynamically to rule out other possible forms of bladder or sphincter dysfunction. In refractory cases, sacral nerve stimulation (InterStim) is a surgical procedure that has shown promise.

If the child has constipation based on the criteria described above, treatment generally is initiated with polyethylene glycol powder, which has been shown to be safe in children and generally more effective than other laxative preparations.

**NONNEUROGENIC NEUROGENIC BLADDER (HINMAN SYNDROME)**

Hinman syndrome is a very serious but uncommon disorder involving failure of the external sphincter to relax during voiding in children without neurologic abnormalities. Children with this syndrome, also called nonneurogenic neurogenic bladder, typically exhibit a staccato stream, day and night wetting, recurrent UTIs, constipation, and encopresis. Evaluation of affected children often reveals vesicoureteral reflux, a trabeculated bladder, and a decreased urinary flow rate with an intermittent pattern (Fig. 543-4). In severe cases, hydronephrosis, renal insufficiency, and end-stage renal disease can occur. The pathogenesis of this syndrome is thought to involve learning abnormal voiding habits during toilet training; the syndrome is rarely seen in infants. Urodynamic studies and magnetic resonance imaging of the spine are indicated to rule out a neurologic cause for the bladder dysfunction.

The treatment usually is complex and can include anticholinergic and α-adrenergic blocker therapy, timed voiding, treatment of constipation, behavioral modification, and encouragement of relaxation during voiding. Biofeedback has been used successfully in older children to teach relaxation of the external sphincter. In some cases botulinum toxin (Botox) injection into the external sphincter can provide temporary sphincteric paralysis and thereby reduce outlet resistance. In severe cases, intermittent catheterization is necessary to ensure bladder emptying. In selected patients, external urinary diversion is necessary to protect the upper urinary tract. These children require long-term treatment and careful follow-up.

**INFREQUENT VOIDING (UNDERACTIVE BLADDER)**

Infrequent voiding is a common disorder of micturition, usually associated with UTIs. Affected children, usually girls, void only twice a day rather than the normal 4-7 times. With bladder overdistention and prolonged retention of urine, bacterial growth can lead to recurrent UTIs. Some of these children are constipated. Some also have occasional episodes of incontinence from overflow or urgency. The disorder is behavioral. If the child has UTIs, treatment includes antibacterial prophylaxis and encouragement of frequent voiding and complete emptying of the bladder by double voiding until a normal pattern of micturition is re-established.

**VAGINAL VOIDING**

In girls with vaginal voiding, incontinence typically occurs after urination after the girl stands up. Usually the volume of urine is 5-10 mL. One of the most common causes is labial adhesion (Fig. 543-5). This lesion, typically seen in young girls, can be managed either by topical application of estrogen cream to the adhesion or lysis in the office. Some girls experience vaginal voiding because they do not separate their legs widely during urination. These girls either are overweight...
or do not pull their underwear down to their ankles when they
urinate. Management involves encouraging the girl to separate the
legs as widely as possible during urination. The most effective way to
do this is to have the child sit backward on the toilet seat during
micturition.

**OTHER CAUSES OF INCONTINENCE IN GIRLS**

Ureteral ectopia, usually associated with a duplicated collecting
system in girls, refers to a ureter that drains outside the bladder, often
into the vagina or distal urethra. It can produce urinary incontinence
characterized by constant urinary dripping all day, even though the
child voids regularly. Sometimes the urine production from the renal
segment drained by the ectopic ureter is small, and urinary drainage
is confused with watery vaginal discharge. Children with a history of
vaginal discharge or incontinence and an abnormal voiding pattern
require careful study. The ectopic orifice usually is difficult to find. On
ultrasonography or intravenous urography, one may suspect duplica-
tion of the collecting system (Fig. 543-6), but the upper collecting
system drained by the ectopic ureter usually has poor or delayed func-
tion. CT scanning of the kidneys or an MR urogram should demon-
strate subtle duplication anomalies. Examination under anesthesia for
an ectopic ureteral orifice in the vestibule or the vagina may be neces-
sary (Fig. 543-7). The treatment in these cases is either partial nephrec-
tomy, with removal of the upper pole segment of the duplicated kidney
and its ureter down to the pelvic brim, or ipsilateral ureteroureteros-
tomy, in which the upper pole ectopic ureter is anastomosed to the
normally positioned lower pole ureter. These procedures often are
performed by minimally invasive laparoscopy with or without robotic
assistance.

Giggle incontinence typically affects girls 7-15 yr of age. The
incontinence occurs suddenly during giggling, and the entire bladder
volume is lost. The pathogenesis is thought to be sudden relaxation of
the urinary sphincter. Anticholinergic medication and timed voiding
occasionally are effective. The most effective treatment is low-dose
methylphenidate.

Total incontinence in girls may be secondary to epispadias (see
Fig. 541-2 in Chapter 541). This condition, which affects only 1 in
480,000 females, is characterized by separation of the pubic symphysis,
separation of the right and left sides of the clitoris, and a patulous
urethra. Treatment is bladder neck reconstruction or placement of an
artificial urinary sphincter to repair the incompetent urethra.
no anatomic problem is detected. Often the symptoms occur just before a child starts kindergarten or if the child is having emotional family stress-related problems. These children should be checked for UTIs, and the clinician should ascertain that the child is emptying the bladder satisfactorily. Occasionally, pinworms cause these symptoms. The condition is self-limited, and symptoms generally resolve within 2-3 mo. Anticholinergic therapy rarely is effective.

Some children have the dysuria-hematuria syndrome, in which the child has dysuria without UTI but with microscopic or gross hematuria. This condition affects children who are toilet-trained and is often secondary to hypercalciuria. A 24-hr urine sample should be obtained and calcium and creatinine excretion assessed. A 24-hr calcium excretion of >4 mg/kg is abnormal and deserves treatment with thiazides, because some of these children are at risk for urolithiasis.

### Nocturnal Enuresis

By 5 yr of age, 90-95% of children are nearly completely continent during the day, and 80-85% are continent at night. Nocturnal enuresis refers to the occurrence of involuntary voiding at night after 5 yr, the age when volitional control of micturition is expected. Enuresis may be primary (estimated 75-90% of children with enuresis; nocturnal urinary control never achieved) or secondary (10-25%; the child was dry at night for at least a few months and then enuresis developed). In addition, 75% of children with enuresis are wet only at night, and 25% arecontinent day and night. This distinction is important, because children with both forms are more likely to have an abnormality of the urinary tract. Monosymptomatic enuresis is more common than nonmonosymptomatic enuresis (associated urgency, hesitancy, frequency, day time incontinence).

### Epidemiology

Approximately 60% of children with nocturnal enuresis are boys. Family history is positive in 50% of cases. Although primary nocturnal enuresis may be polygenetic, candidate genes have been localized to chromosomes 12 and 13. If one parent was enuretic, each child has a 44% risk of enuresis; if both parents were enuretic, each child has a 77% likelihood of enuresis. Nocturnal enuresis without overt daytime voiding symptoms affects up to 20% of children at the age of 5 yr; it ceases spontaneously in approximately 15% of involved children every year thereafter. Its frequency among adults is <1%.

### Other Features

Enuresis can occur in any stage of sleep (but usually non–rapid eye movement sleep) All children are most difficult to arouse in the first third of the night and easiest to awaken in the last third, but enuretic children are more difficult to arouse than those with normal bladder control. Enuretic children often are described as “soaking the bed” Family history in enuretic children often positive for enuresis Risk increased with developmental delay, attention-deficit/ hyperactivity disorder, autism spectrum disorders

### Pathogenesis

The pathogenesis of nocturnal enuresis (normal daytime voiding habits) is multifactorial (Table 543-2).

### Clinical Manifestations and Diagnosis

A careful history should be obtained, especially with respect to fluid intake at night and pattern of nocturnal enuresis. Children with diabetes insipidus (see Chapter 558), diabetes mellitus (see Chapter 589), and chronic renal disease (see Chapter 535) can have a high obligatory urinary output and a compensatory polydipsia. The family should be asked whether the child snores loudly at night. A complete physical examination should include palpation of the abdomen and rectal examination after voiding to assess the possibility of a chronically distended bladder. The child with nocturnal enuresis should be examined carefully for neurologic and spinal abnormalities. There is an increased incidence of bacteriuria in enuretic girls, and, if found, it should be investigated and treated (see Chapter 538), although this does not always lead to resolution of bedwetting. A urine sample should be obtained after an overnight fast and evaluated for specific gravity or osmolality to exclude polyuria as a cause of frequency and incontinence and to ascertain that the concentrating ability is normal. The absence of glycosuria should be confirmed. If there are no daytime symptoms, the physical examination and urinalysis are normal, and the urine culture is negative, further evaluation for urinary tract pathology generally is not warranted. A renal ultrasonogram is reasonable in an older child with enuresis or in children who do not respond appropriately to therapy.

### Treatment

The best approach to treatment is to reassure the child and parents that the condition is self-limited and to avoid punitive measures that can affect the child’s psychologic development adversely. Fluid intake should be restricted to 2 oz after 6 or 7 PM. The parents should be certain that the child voids at bedtime. Avoiding extraneous sugar and caffeine after 4 PM also is beneficial. If the child snores and the adenoids are enlarged, referral to an otolaryngologist should be considered, because adenoidectomy can cure the enuresis.
Active treatment should be avoided in children younger than 6 yr of age, because enuresis is extremely common in younger children. Treatment is more likely to be successful in children approaching puberty compared with younger children. In addition, treatment is most likely to be effective in children who are motivated to stay dry. Treatment should be viewed as a facilitator that requires active participation by the child (e.g., a coach and an athlete).

The simplest initial measure is motivational therapy and includes a star chart for dry nights. Waking children a few hours after they go to sleep to have them void often allows them to awaken dry, although this measure is not curative. Some have recommended that children try holding their urine for longer periods during the day, but there is no evidence that this approach is beneficial. Conditioning therapy involves use of a loud auditory or vibratory alarm attached to a moisture sensor in the underwear. The alarm sounds when voiding occurs and is intended to awaken children and alert them to void. This form of therapy has reported success of 30-60%, although the relapse rate is significant. Often the auditory alarm wakes up other family members and not the enuretic child; persistent use of the alarm for several months often is necessary to determine whether this treatment is effective. Conditioning therapy tends to be most effective in older children. Another form of therapy to which some children respond is self-hypnosis. The primary role of psychologic therapy is to help the child deal with enuresis psychologically and help motivate the child to void at night if he or she awakens with a full bladder.

Pharmacologic therapy is intended to treat the symptom of enuresis and thus is regarded as second line and is not curative. Direct comparisons of the bell and bed with pharmacologic therapy favor the former because of lower relapse rates, although initial response rates are equivalent.

One form of treatment is desmopressin acetate, a synthetic analog of antidiuretic hormone that reduces urine production overnight. This medication is FDA-approved and is available as a tablet, with a dosage of 0.2-0.6 mg at bedtime. In the past a nasal spray was used, but some children experienced hyponatremia and convulsions with this formulation and the nasal spray is no longer recommended for nocturnal enuresis. Hyponatremia has not been reported in children using the oral tablets. Fluid restriction at night is important, and the drug should not be used if the child has a systemic illness with vomiting or diarrhea or if the child has polydipsia. Desmopressin acetate is effective in as many as 40% of children. If effective, it should be used for 3-6 mo, and then an attempt should be made to taper the dosage. If tapering results in recurrent enuresis, the child should return to the higher dosage. Few adverse events have been reported with the long-term use of desmopressin acetate.

For therapy-resistant enuresis or children with symptoms of an overactive bladder, anticholinergic therapy is indicated. Oxybutynin 5 mg or tolterodine 2 mg at bedtime often are prescribed. If the medication is ineffective, the dosage may be doubled. The clinician should monitor for constipation as a potential side effect.

A third-line treatment is imipramine, which is a tricyclic antidepressant. This medication has mild anticholinergic and α-adrenergic effects, reduces urine output slightly, and also might alter the sleep pattern. The dosage of imipramine is 25 mg in children age 6-8 yr, 50 mg in children age 9-12 yr, and 75 mg in teenagers. Reported success rates are 30-60%. Side effects include anxiety, insomnia, and dry mouth, and heart rhythm may be affected. If there is any history of palpitations or syncope in the child, or sudden cardiac death or unstable arrhythmia in the family, long QT syndrome in the patient needs to be excluded. The drug is one of the most common causes of poisoning by prescription medication in younger siblings.

In unsuccessful cases, combining therapies often is effective. Alarm therapy plus desmopressin is more successful than either alone. The combination of oxybutynin chloride and desmopressin is more successful than either alone. Desmopressin and imipramine also may be combined.
Bibliography

HYPOSPADIAS

Hypospadias is a urethral opening on the ventral surface of the penile shaft affecting 1 in 250 male newborns. Typically an isolated defect, but its incidence is increased in disorders of sex differentiation, anorectal malformation, and congenital heart disease. Usually there is incomplete development of the prepuce, called a dorsal hood, in which the foreskin is on the sides and dorsal aspect of the penile shaft and deficient or absent ventrally. Some boys with hypospadias, particularly those with proximal hypospadias, have chordee, in which there is ventral penile curvature during erection. The incidence of hypospadias appears to be increasing, possibly because of in utero exposure to estrogenic or antiandrogenic endocrine-disrupting chemicals (e.g., polychlorobiphenyls, phytoestrogens).

Clinical Manifestations

Hypospadias is classified according to the position of the urethral meatus after taking into account whether chordee is present (Fig. 544-1). The deformity is described as glanular (on the glans penis), coronal, subcoronal, midpenile, penoscrotal, scrotal, or perineal. Approximately 65% of cases are distal, 25% are subcoronal or midpenile, and 10% are proximal. In the most severe cases, the scrotum is bifid and sometimes there is moderate penoscrotal transposition. As many as 10% of affected boys have a megameatal variant, in which the foreskin is developed normally (megameatus intact prepuce variant), and there is either glanular or subcoronal hypospadias with a “fish mouth” meatus. These cases might not be diagnosed until after a circumcision is performed.

Approximately 10% of boys with hypospadias have an undescended testis; inguinal hernias also are common. In the newborn, the differential diagnosis of midpenile or proximal hypospadias associated with an undescended testis should include forms of a disorder of sex development, particularly mixed gonadal dysgenesis, partial androgen insensitivity, true hermaphroditism, and congenital adrenal hyperplasia in a female (see Chapter 576). In the latter situation, neither gonad would be palpable. A karyotype should be obtained in patients with midpenile or proximal hypospadias and cryptorchidism (see Chapter 588). In boys with penoscrotal hypospadias, a voiding cystourethrogram should be considered because 5-10% of these children have a dilated prostatic utricle, which is a remnant of the müllerian system (see Chapter 554). The incidence of upper urinary tract abnormalities is low unless there are abnormalities of other organ systems.

Complications of untreated hypospadias include deformity of the urinary stream, typically ventral deflection or severe splaying; sexual dysfunction secondary to penile curvature; infertility if the urethral meatus is proximal; meatal stenosis (congenital), which is uncommon; and cosmetic appearance. The goal of hypospadias surgery is to correct the functional and cosmetic deformities. Whereas hypospadias repair is recommended for all boys with midpenile and proximal hypospadias, some boys with distal hypospadias have no functional abnormality and do not need any surgical correction.

Treatment

Management begins in the newborn period. Circumcision should be avoided, because the foreskin often is used in the repair in most cases. The ideal age for repair in a healthy infant is 6-12 mo, because the risk of general anesthesia at this age is similar to older children; penile growth over the next several years is slow; the child does not remember the surgical procedure; and postoperative analgesic needs are less than
in older children. With the exception of proximal hypospadias, virtually all cases are repaired in a single operation on an ambulatory basis. The most common repair involves tubularization of the urethral plate distal to the urethral meatus, with coverage by a vascularized flap from the foreskin, termed a tubularized incised plate repair. Proximal cases might require a 2-stage repair. The complication rate is low: 5% for distal hypospadias, 10% for midpenile hypospadias, and 20% for proximal hypospadias. The most common complications include urethrocutaneous fistula and meatal stenosis. Other complications include a deformed urinary stream, persistent penile curvature, and dehiscence of the hypospadias repair. Treatment of these complications generally is straightforward. In complex cases, a buccal mucosa graft is used to create urethral mucosa. Repair of hypospadias is a technically demanding operation and should be performed by a surgeon with specialty training in pediatric urology and extensive experience.

**CHORDEE WITHOUT HYPOSPADIAS**

In some boys there is mild or moderate ventral penile curvature (chordee) and incomplete development of the foreskin (dorsal hood), but the urethral meatus is at the tip of the glans (Fig. 544-2). In most of these boys, the urethra is normal but there is insufficient ventral penile skin or prominent, inelastic ventral bands of dartos fascia that prevent a straight erection. In some cases, the urethra is hypoplastic, and a formal urethroplasty is necessary for repair. The only sign of this anomaly in the neonate may be the hooded foreskin, and delayed repair under general anesthesia at 6 mo of age is recommended.

**PHIMOSIS AND PARAPHIMOSIS**

Phimosis refers to the inability to retract the prepuce. At birth, phimosis is physiologic. Over time, the adhesions between the prepuce and glans lyse and the distal phimotic ring loosens. In 80% of uncircumcised boys the prepuce becomes retractable by 3 yr of age. Accumulation of epithelial debris under the infant’s prepuce is physiologic and does not mandate circumcision. In older boys, phimosis may be physiologic, may be pathologic from inflammation and scarring at the tip of the foreskin (Fig. 544-3), or occurs after circumcision. The prepuce might have been retracted forcefully on 1 or 2 occasions in the past, which can result in a cicatricial scar that prevents subsequent retraction of the foreskin. In boys with persistent physiologic or pathologic phimosis, application of corticosteroid cream to the foreskin 3 times daily for 1 mo loosens the phimotic ring in two-thirds of cases. If there is ballooning of the foreskin during voiding or phimosis beyond 10 yr of age and topical corticosteroid therapy is ineffective, circumcision is recommended.

Paraphimosis occurs when the foreskin is retracted proximal to the coronal sulcus and the prepuce cannot be pulled back over the glans.

hyaluronidase into the edematous skin has been reported to result in immediate reduction in swelling. In rare cases, emergency circumcision under general anesthesia is necessary.

CIRCUMCISION

In the United States, circumcision usually is performed for cultural reasons. In 2012, a multidisciplinary task force of the American Academy of Pediatrics stated that evidence indicates that the health benefits of newborn male circumcision outweigh the risks and that the procedure’s benefits justify access to this procedure for families who choose it. Specific benefits identified included prevention of urinary tract infections (UTIs), penile cancer, reducing the risk and transmission of some sexually transmitted infections, including HIV. The American College of Obstetricians and Gynecologists endorsed this policy statement. By contrast, European medical professional groups have been less likely to endorse this practice.

When performing a neonatal circumcision, local analgesia, such as a dorsal nerve block or application of EMLA (eutectic mixture of local anesthetics) cream (lidocaine 2.5% and prilocaine 2.5%) is recommended.

UTIs are 10-15 times more common in uncircumcised infant boys than in circumcised infants, with the urinary pathogens arising from bacteria that colonize the space between the prepuce and glans. The risk of febrile UTI (see Chapter 538) is highest between birth and 6 mo, but there is an increased risk of UTI until at least 5 yr of age. Many recommend circumcision in infants who are predisposed to UTI, such as those with congenital hydronephrosis and vesicoureteral reflux. Circumcision reduces the risk of sexually transmitted infections in adults (see Chapter 120), in particular HIV (see Chapter 276). There have been only a handful of reports of men who were circumcised at birth and subsequently acquired penile carcinoma, but in Scandinavian countries, where few men are circumcised and hygiene is good, the incidence of penile cancer is low.

Complications after neonatal circumcision include bleeding, wound infection, meatal stenosis, secondary phimosis, removal of insufficient foreskin, and fibrous penile adhesions (skin bridge; Fig. 544-5); 0.2-3.0% of patients undergo a subsequent operative procedure. Boys with a large hydrocele or hernia are at particular risk for secondary phimosis because the scrotal swelling tends to displace the penile shaft skin over the glans. Potentially serious complications include sepsis, amputation of the distal part of the glans, removal of an excessive amount of foreskin, and urethrocutaneous fistula. Circumcision should not be performed in neonates with hypospadias, chordee without hypospadias, or a dorsal hood deformity (relative contraindication) or in those with (Fig. 544-4). Painful venous stasis in the retracted foreskin results, with edema leading to severe pain and inability to reduce the foreskin (pull it back over the glans). Treatment includes lubricating the foreskin and glans and then simultaneously compressing the glans and placing distal traction on the foreskin to try to push the phimotic ring past the coronal sulcus. Topical application of granulated sugar has been reported to aid in reduction of edema by creation of an osmotic gradient, facilitating reduction of paraphimosis. In addition, injection of
Anomalies of the Penis and Urethra

2589

Anomalies of the Penis and Urethra

2589

might appear mild, if a routine circumcision is performed, the penis can retract into the scrotum, resulting in secondary phimosis (trapped penis). The concealed (hidden or buried) penis is a normally developed penis that is camouflaged by the suprapubic fat pad (Fig. 544-7). This anomaly may be congenital, iatrogenic after circumcision, or a result of obesity. Surgical correction is indicated for cosmetic reasons or if there is a functional abnormality with a splayed stream.

A trapped penis is an acquired form of inconspicuous penis and refers to a phallic that becomes embedded in the suprapubic fat pad after circumcision (Fig. 544-8). This deformity can occur after neonatal circumcision in an infant who has significant scrotal swelling from a large hydrocele or inguinal hernia or after routine circumcision in an infant with a webbed penis. This complication can predispose to UTIs and can cause urinary retention. Initial treatment of a trapped penis should include topical corticosteroid cream, which often loosens the phimotic ring. In some cases secondary repair is necessary at 6-9 mo.

MICROPENIS

Micropenis is defined as a normally formed penis that is at least 2.5 SD below the mean in size (Fig. 544-9). Typically, the ratio of the length
of the penile shaft to its circumference is normal. The pertinent measurement is the stretched penile length, which is measured by stretching the penis and measuring the distance from the penile base under the pubic symphysis to the tip of the glans. The mean length of the term newborn penis is 3.5 ± 0.7 cm and the diameter is 1.1 ± 0.2 cm. The diagnosis of micropenis is made if the stretched length is <1.9 cm.

Micropenis usually results from a hormonal abnormality that occurs after 14 wk of gestation. Common causes include hypogonadotropic hypogonadism, hypergonadotropic hypogonadism (primary testicular failure), and idiopathic micropenis. If growth hormone deficiency also is present, neonatal hypoglycemia can occur. The most common cause of micropenis is failure of the hypothalamus to produce an adequate amount of gonadotropin-releasing hormone, as typically occurs in Kallmann syndrome (see Chapter 583), Prader-Willi syndrome (see Chapter 108), and Lawrence-Moon-Bardet-Biedl syndrome. In some cases, there is growth hormone deficiency. Primary testicular failure can result from gonadal dysgenesis or rudimentary testes syndrome and also occurs in Robinow syndrome (characterized by hypoplastic genitalia, shortening of the forearms, frontal bossing, hypertelorism, wide palpebral fissures, short broad nose, long philtrum, small chin, brachydactyly, and a normal karyotype).

A pediatric endocrinologist, geneticist, and pediatric urologist should examine all children with these syndromes. Evaluation includes a karyotype, assessment of anterior pituitary function and testicular function, and MRI to determine the anatomic integrity of the hypothalamus and the anterior pituitary gland as well as the midline structure of the brain. One of the difficult questions is whether androgen therapy is essential during childhood, because androgenic stimulation of penile growth in a prepubertal boy can limit the growth potential of the penis in puberty. Studies of small groups of men with micropenis suggest that many, although not all, have satisfactory sexual function. Consequently, a decision for gender reassignment is made infrequently.

PRIAPISM
Priapism is a persistent penile erection at least 4 hr in duration that continues beyond, or is unrelated to, sexual stimulation. Typically, only the corpora cavernosa are affected. There are 3 subtypes:
Anomalies

- **Ischemic** (venoocclusive, low-flow) priapism is characterized by little or no cavernous blood flow, and cavernous blood gases are hypoxic, hypercapnic, and acidic. The corpora are rigid and tender to palpation.
- **Nonischemic** (arterial, high-flow) priapism is caused by unregulated cavernous arterial inflow. Typically, the penis is neither fully rigid nor painful. There is often a history of antecedent trauma resulting in a cavernous artery–corpora cavernosa fistula.
- **Stuttering (intermittent)** priapism is a recurrent form of ischemic priapism with painful erections with intervening periods of detumescence.

The most common cause of priapism in children is sickle cell disease, which is characterized by predominance of sickle cell hemoglobin (see Chapter 462.1). As many as 27.5% of children with sickle cell disease develop priapism. The priapism is generally related to a low-flow state, secondary to sickling of red blood cells within the sinusoids of the corpora cavernosa during normal erection, resulting in venous stasis. This situation results in decreased local oxygen tension and pH, which potentiates further stasis and sickling. Priapism typically occurs during sleep, when mild hypoventilatory acidosis depresses oxygen tension and pH in the corpora. There is typically significant corporal engorgement with sparing of the glans penis. If the spongiosum is involved, voiding may be impaired. Evaluation includes complete blood count and serum chemistry. If sickle cell status is unknown, hemoglobin electrophoresis should be performed. In some cases, corporal aspiration is performed to distinguish between a high-flow and low-flow state. Other causes of low-flow priapism include sildenafil ingestion and leukemia.

In priapism secondary to sickle cell disease, medical therapy includes exchange transfusion, intravenous hydration, alkalization, pain management with morphine, and oxygen. The American Urological Association guideline on priapism also recommends concurrent intracavernous treatment beginning with corporal aspiration and irrigation with a sympathomimetic agent, such as phentolamine. If priapism has been present >48 hr, ischemia and acidosis impair the intracavernous smooth muscle response to sympathomimetics. If irrigation and medical therapy are unsuccessful, a corpororoglanular shunt should be considered. For stuttering priapism, administration of an oral α-adrenergic agent (pseudoephedrine) once or twice daily is first-line therapy. If this treatment is unsuccessful, an oral β-agonist (terbutaline) is recommended; a gonadotropin-releasing hormone analog plus flutamide is recommended as third-line therapy. Long-term follow-up of adults treated for sickle cell disease as children shows that satisfactory erectile function is inversely related to the patient’s age at onset of priapism and duration of priapism.

Nonischemic (high-flow) priapism most commonly follows perineal trauma, such as a straddle injury, that results in laceration of the cavernous artery. Typically, the aspirated blood is bright red, and the aspirate is similar to arterial blood. Color Doppler ultrasonography often demonstrates the fistula. The priapism can spontaneously resolve. If it does not, angiographic embolization is indicated.

**OTHER PENILE ANOMALIES**

**Agenesis of the penis** affects approximately 1 in 10 million boys. The karyotype is almost always 46,XY, and the usual appearance is that of a well-developed scrotum with descended testes and an absent penile shaft. Upper urinary tract abnormalities are common. In most cases, gender reassignment is recommended in the newborn period. **Diphallia** ranges from a small accessory penis to complete duplication. **Lateral penile curvature** usually is caused by overgrowth or hypoplasia of a corporal (erectile) body and usually is congenital. Surgical repair is recommended at age 6-12 mo.

**MEATAL STENOSIS**

Meatal stenosis is a condition that almost always is acquired and occurs after neonatal circumcision. It probably results from severe inflammation of the denuded glans, and is difficult to prevent. If the meatus is pinpoint, boys void with a forceful, fine stream that goes a great distance. These boys can experience dysuria, frequency, hematuria, or a combination of these conditions, typically at age 3-8 yr. UTI is uncommon. Other boys have dorsal deflection of the urinary stream. Although the meatus may be small, hydrenephrosis or voiding difficulty is extremely rare unless there is associated balanitis xerotica obliterans (see Fig. 544-3; chronic dermatitis of unknown etiology, generally involving the glans and prepuce, occasionally extending into the urethra). **Treatment** is meatoplasty, in which the urethral meatus is opened surgically; this procedure can be performed either under anesthesia as an outpatient or in the office using local anesthesia (EMLA cream) with or without sedation. Routine cystoscopy is unnecessary.

**OTHER MALE URETHRAL ANOMALIES**

**Paramesal urethral cyst** manifests as an asymptomatic small cyst on one side of the urethral meatus. Treatment is excision under anesthesia. **Congenital urethral fistula** is a rare deformity in which a fistula is present from the penile urethra. It usually is an isolated abnormality. Treatment is fistula closure. **Megalourethra** is a large urethra that usually is associated with abnormal development of the corpus spongiosum. This condition is most commonly associated with prune-belly syndrome (see Chapter 540). **Urethral duplication** is a rare condition in which the 2 urethral channels lie in the same sagittal plane. There are many variations with complete and incomplete urethral duplication. These boys often have a double stream. Most commonly the dorsal urethra is small and the ventral urethra is normal caliber. Treatment involves excision of the small urethra. **Urethral hypoplasia** is a rare condition in which the urethra is extremely small but patent. In some cases, a temporary cutaneous vesicostomy is necessary for satisfactory urinary drainage. Either gradual enlargement of the urethra or major urethroplasty is necessary. **Urethral atresia** refers to maldevelopment of the urethra and nearly always is fatal unless the urachus remains patent throughout gestation.

**URETHRAL PROLAPSE (FEMALE)**

Urethral prolapse is encountered predominantly in black girls 1-9 yr of age. The most common signs are bloody spotting on the underwear or diaper, although dysuria or perineal discomfort also can occur (Fig. 544-10). An inexperienced examiner can mistake the finding for sexual...
abuse. The usual therapy consists of application of estrogen cream 2-3 times daily for 3-4 wk and sitz baths. Surgical excision and reapproximation of the mucosal edges is recommended for girls that fail medical therapy and is curative.

OTHER FEMALE URETHRAL LESIONS
Paraurethral cyst results from retained secretions in the Skene glands secondary to ductal obstruction (Fig. 544-11). These lesions are present at birth, and most regress in size during the 1st 4-8 wk, although occasionally incision and drainage is necessary. A prolapsed ectopic ureterocele appears as a cystic mass protruding from the urethra and is a presenting symptom in 10% of girls with a ureterocele, which is a cystic swelling of the terminal ureter (Fig. 544-12). Ultrasonography should be performed to visualize the upper urinary tracts to confirm the diagnosis. Usually, either the ureterocele is incised or an upper urinary tract reconstructive procedure is necessary.

Bibliography

(Reviewed and validity confirmed 2010 by AUA).

UNDESCENDED TESTIS (CRYPTORCHIDISM)
The absence of a palpable testis in the scrotum indicates that the testis is undescended, absent, or retracted.

Epidemiology
An undescended (cryptorchid) testis is the most common disorder of sexual differentiation in boys. At birth, approximately 4.5% of boys have an undescended testis. Because testicular descent occurs at 7-8 mo of gestation, 30% of premature male infants have an undescended testis; the incidence is 3.4% at term. The majority of congenital undescended testes descend spontaneously during the 1st 3 mo of life, and by 6 mo the incidence decreases to 0.8%. Spontaneous descent occurs secondary to a temporary testosterone surge during the 1st 2 mo, which also results in significant penile growth. If the testis has not descended by 4 mo, it will remain undescended. Cryptorchidism is bilateral in 10% of cases. There is some evidence that the incidence of cryptorchidism is increasing. Although cryptorchidism usually is considered to be congenital, some boys have a scrotal testis that "ascends" to a low inguinal position, and therefore requires an orchiopecty. In addition, 1-2% of neonatal and young boys undergoing hernia repair have secondary cryptorchidism.

Pathogenesis
The process of testicular descent is regulated by an interaction between hormonal and mechanical factors, including testosterone, dihydrotestosterone, müllerian-inhibiting factor, the gubernaculum, intraabdominal pressure, and the genitofemoral nerve. The testis develops at 7-8 wk of gestation. At 10-11 wk, the Leydig cells produce testosterone, which stimulates differentiation of the wolffian (mesonephric) duct into the epididymis, vas deferens, seminal vesicle, and ejaculatory duct. At 32-36 wk, the testis, which is anchored at the internal inguinal ring by the gubernaculum, begins its process of descent. The gubernaculum distends the inguinal canal and guides the testis into the scrotum. Following testicular descent, the patent processus vaginalis (hernia sac) normally involutes. A small percentage have Klinefelter syndrome or mutations in the insulin-like factor 3 receptor.

Clinical Manifestations
Undescended testes are classified as abdominal (nonpalpable), peeping (abdominal but can be pushed into the upper part of the inguinal canal), inguinal, gliding (can be pushed into the scrotum but retracts immediately to the pubic tubercle), and ectopic (superficial inguinal pouch or, rarely, perineal). Most undescended testes are palpable just distal to the inguinal canal over the pubic tubercle.

A disorder of sex development should be suspected in a newborn phenotypic male with bilateral nonpalpable testes, as the child could be a virilized girl with congenital adrenal hyperplasia (see Chapter 576). In a boy with midpenile or proximal hypospadias and a palpable undescended testis, disorder of sexual development is present in 15%, and the risk is 50% if the testis is nonpalpable.

The consequences of cryptorchidism include poor testicular growth, infertility, testicular malignancy, associated hernia, torsion of the cryptorchid testis, and the possible psychologic effects of an empty scrotum.

The undescended testis is normal at birth histologically, but pathologic changes can be demonstrated by 6-12 mo. Delayed germ cell maturation, reduction in germ cell number, hyalinization of the
seminiferous tubules, and reduced Leydig cell number are typical; these changes are progressive over time if the testis remains undescended. Similar, although less severe, changes are found in the contralateral descended testis after 4-7 yr. After treatment for a unilateral undescended testis, 85% of patients are fertile, which is slightly less than the 90% rate of fertility in an unselected population of men. In contrast, following bilateral orchiopexy, only 50-65% of patients are fertile.

The risk of a germ cell malignancy (see Chapter 503) developing in an undescended testis is 4 times higher than in the general population, and is approximately 1 in 80 with a unilateral undescended testis and 1 in 40-50 for bilateral undescended testes. Testicular tumors are less common if the orchiopexy is performed before 10 yr of age, but they still occur, and adolescents should be instructed in testicular self-examination. The peak age for developing a testis tumor is 15-45 yr. The most common tumor developing in an undescended testis in an adolescent or adult is a seminoma (65%); after orchiopexy, nonseminomatous tumors represent only 65% of testis tumors. Orchiopexy seems to reduce the risk of seminoma. Whether early orchiopexy reduces the risk of developing cancer of the testis is controversial, but it is uncommon for testis tumors to occur if the orchiopexy performed before the age of 2 yr. The contralateral scrotal testis is not at increased risk for malignancy.

An indirect inguinal hernia usually accompanies a congenital undescended testis but rarely is symptomatic. Torsion and infarction of the cryptorchid testis also are uncommon but can occur because of excessive mobility of undescended testes. Consequently, inguinal pain and/or swelling in a boy with an undescended testis should raise the suspicion of an incarcerated hernia or testicular torsion of the undescended testis.

"Acquired" or ascending undescended testes occurs when a boy has a descended testis at birth, but during childhood, usually between 4-10 yr of age, the testis does not remain in the scrotum. Such boys often have a history of a retractile testis. With testicular ascent, on physical examination the testis often can be manipulated into the scrotum, but there is obvious tension on the spermatic cord. This condition is speculated to result from incomplete involution of the processus vaginalis, restricting spermatic cord growth, resulting in the testis gradually moving out of its scrotal position during a boy's somatic growth.

Retractile testes may be misdiagnosed as undescended testes. Boys older than age 1 yr often have a brisk cremasteric reflex, and if the child is anxious or ticklish during scrotal examination, the testis may be difficult to manipulate into the scrotum. Boys should be examined with their legs in a relaxed frogleg position, and if the testis can be manipulated into the scrotum comfortably, it is probably retractile. It should be monitored every 6-12 mo with follow-up physical examinations, because it can become an acquired undescended testis. Overall, as many as one-third of boys with a retractile testis develop an acquired undescended testis, and boys younger than 7 yr of age at diagnosis of a retractile testis are at greatest risk. Although definitive data are not available, it is generally thought that boys with a retractile testis are not at increased risk for infertility or malignancy.

Approximately 10% of undescended testes are nonpalpable testis. Of these, 50% are viable testes in the abdomen or high in the inguinal canal, and 50% are atrophic or absent, almost always in the scrotum, secondary to spermatic cord torsion in utero (vanishing testis). If the nonpalpable testis is abdominal, it will not descend after 3 mo of age. Although sonography often is performed to try to identify whether the testis is present, it rarely changes clinical management, because the abdominal testis and atrophic testis are not identified on sonography. As part of the ABIM Choosing Wisely campaign, in 2012 the American Urological Association recommended that inguinal/scrotal sonography not be performed routinely in boys with a nonpalpable testis, because it rarely alters the surgical management. However, inguinal/scrotal sonography might be beneficial in obese boys with a nonpalpable testis; in this clinical setting, the undescended testis often is nonpalpable, and an inguinal/scrotal sonogram can be beneficial in surgical planning. CT scanning is relatively accurate in demonstrating the presence of the testis, but the radiation exposure is significant. MRI is even more accurate, but the disadvantage is that general anesthesia is necessary in most young children. None of these imaging studies are 100% accurate and in general do not add significantly to clinical decision making by the pediatric urologist or pediatric surgeon. Consequently, its routine use is discouraged.

On physical examination of the scrotum, the child should be entirely undressed, to help him relax. The examiner should examine the patient's scrotum and inguinal canal using their dominant hand. The nondominant hand is positioned over the pubic tubercle and is pinched internally toward the scrotum. The examiner's dominant hand is used to try to palpate the testis. If the testis is nonpalpable, the "soap test" often is useful; soap is applied to the inguinal canal and the examiner's hand, significantly reducing friction and facilitating identification of an inguinal testis. In addition, pulling on the scrotum can pull a high inguinal testis into a palpable position. One soft sign that a testis is absent is contralateral testicular hypertrophy, but this finding is not 100% diagnostic.

Treatment

The congenital undescended testis should be treated surgically by 9-15 mo of age. With anesthesia by a pediatric anesthesiologist, surgical correction at 6 mo is appropriate, because spontaneous descent of the testis will not occur after 4 mo of age. Most testes can be brought down to the scrotum with an orchiopexy, which involves an inguinal incision, mobilization of the testis and spermatic cord, and correction of an indirect inguinal hernia. The procedure is typically performed on an outpatient basis and has a success rate of 98%. In some boys with a testis that is close to the scrotum, a prescrotal orchiopexy can be performed. In this procedure, the entire operation is performed through an incision along the edge of the scrotum. Often the associated inguinal hernia also can be corrected with this incision. Advantages of this approach over the inguinal approach include shorter operative time and less postoperative discomfort.

In boys with a nonpalpable testis, diagnostic laparoscopy is performed in most centers. This procedure allows safe and rapid assessment of whether the testis is intraabdominal. In most cases, orchiopexy of the intraabdominal testis located immediately inside the internal inguinal ring is successful, but orchietomy should be considered in more difficult cases or when the testis appears to be atrophic. A 2-stage orchiopexy sometimes is needed in boys with a high abdominal testis. Boys with abdominal testes are managed with laparoscopic techniques at many institutions. Testicular prostheses are available for older children and adolescents when the absence of the gonad in the scrotum might have an undesirable psychologic effect. The FDA has approved a saline testicular implant. Solid silicone “carving block” implants also are used (Fig. 545-1). Placement of testicular prostheses early in childhood is recommended for boys with anorchia (absence of both testes).

The American Urological Association released guidelines for the evaluation and treatment of boys with an undescended testis in 2014. Table 545-1 summarizes the primary statements.

SCROTAL SWELLING

Scrotal swelling may be acute or chronic and painful or painless. Abrupt onset of painful scrotal swelling necessitates prompt evaluation because some conditions, such as testicular torsion and incarcerated inguinal hernia, require emergency surgical management. Tables 545-2 and 545-3 show the differential diagnosis.

Clinical Manifestations

A detailed history is helpful in determining the cause of the swelling and includes onset of pain—with testicular torsion, the pain often is sudden in onset and may be associated with exercise or minor genital trauma; duration of pain; radiation of pain—inguinal discomfort is common with testicular torsion, inguinal hernia, or epididymitis, and associated flank pain can occur with passage of a ureteral calculus; previous episodes of similar pain, which are common in boys with intermittent testicular torsion or inguinal hernia; nausea and vomiting, which are associated with testicular torsion and inguinal hernia; and irritative urinary symptoms, such as dysuria, urgency, and frequency.

<tbody>
<tr>
<td>Primary care providers should palpate testes for quality and position at each recommended well-child visit. (Standard) Providers should refer infants with a history of cryptorchidism (detected at birth) who do not have spontaneous testicular descent by 6 mo (corrected for gestational age) to an appropriate surgical specialist for timely evaluation. (Standard) Providers should refer boys with the possibility of newly diagnosed (acquired) cryptorchidism after 6 mo. (Standard) Providers must immediately consult an appropriate specialist for all phenotypic male newborns with bilateral, nonpalpable testes for evaluation of a possible disorder of sex development (DSD). (Standard) Providers should not perform ultrasound (US) or other imaging modalities in the evaluation of boys with cryptorchidism before referral because these studies rarely assist in decision making. (Standard) Providers should assess the possibility of a disorder of sex development (DSD) when there is increasing severity of hypospadias with cryptorchidism. (Recommendation) In boys with retractile testes, providers should monitor the position of the testes at least annually to monitor for secondary ascent. (Standard)</td>
<td></td>
</tr>
<tr>
<td>Providers should not use hormonal therapy to induce testicular descent, since evidence shows low response rates and lack of evidence for long-term efficacy. (Standard) In the absence of spontaneous testicular descent by 6 mo (corrected for gestational age), specialists should perform surgery within the next year. (Standard) In prepubertal boys with nonpalpable testes, surgical specialists should perform examination under anesthesia to reassess for palpability of testes. If nonpalpable, surgical exploration and, if indicated, abdominal orchidopexy should be performed. (Standard) In boys with a normal contralateral testis and either very short testicular vessels and vas deferens, dysmorphic or very hypoplastic testes, or postpubertal age. (Clinical Principle) Providers should counsel boys with a history of cryptorchidism and/or monorchidism and their parents regarding potential long-term risks and provide education on infertility and cancer risk. which indicate a urinary tract infection that can cause epididymitis. Some boys report a recent history of scrotal trauma. There are multiple reports of familial testicular torsion. Boys with lower urinary tract pathology such as urethral stricture or neuropathic bladder may be prone to epididymitis.

Physical examination may be difficult in boys with a painful scrotum. Some have advocated performing a spermatic cord block or administering intravenous analgesia to facilitate the examination, but such measures usually are unnecessary. Scrotal wall erythema is common in testicular torsion, epididymitis, torsion of the appendix testis, and an incarcerated hernia. In boys with a normal cremasteric reflex, testicular torsion is unlikely. Absence of a cremasteric reflex is nondiagnostic.

Laboratory Findings and Diagnosis

Pertinent laboratory studies include a urinalysis and culture. A positive urinalysis suggests bacterial epididymitis. Serum studies are not helpful in establishing a diagnosis, unless a testicular malignancy is suspected. After initial evaluation, in boys with testicular pain color Doppler ultrasonography often is helpful in establishing the diagnosis, because it assesses whether testicular blood flow is normal, reduced, or increased (Fig. 545-2). If a hydrocele is present and the testis is nonpalpable, or if an abnormality of the testis is found, sonography also is indicated. Imaging studies are not 100% accurate; they should not be used to decide whether a boy with testicular pain should be referred for urologic evaluation.

Color Doppler ultrasonography allows assessment of testicular blood flow and testicular morphologic features. Accuracy is >95% if
the ultrasonographer is experienced and the patient is older than 2 yr old. A false-negative study (demonstrates normal testicular blood flow) can occur in a boy with testicular torsion if the degree of torsion is <360 degrees and the duration of torsion is short, because there may be continued testicular perfusion. In young boys, including neonates, blood flow may be difficult to demonstrate in 15% of normal testes.

TESTICULAR (SPERMATIC CORD) TORSION

Etiology

Testicular torsion requires prompt diagnosis and treatment to salvage the testis. Torsion is the most common cause of testicular pain in boys age 12 yr and older, and is uncommon before age 10 yr. It is caused by inadequate fixation of the testis within the scrotum, resulting from a redundant tunica vaginalis, allowing excessive mobility of the testis. The abnormal attachment is termed a bell clapper deformity and often is bilateral. Shortly after torsion occurs, venous congestion begins and subsequently arterial flow is interrupted. The likelihood of testis survival depends on the duration and severity of torsion. Following 4-6 hr of absent blood flow to the testis, irreversible loss of spermatogenesis can occur. Torsion may be familial in approximately 10% of males.

Diagnosis

Testicular torsion produces acute pain and swelling of the scrotum. On examination, the scrotum is swollen, and the testis is exquisitely tender and often difficult to examine. The cremasteric reflex nearly always is absent. The position (lie) of the testis is abnormal and there is often associated nausea and vomiting. The condition can be differentiated from an incarcerated hernia because swelling in the inguinal area typically is absent with torsion. If the pain duration is <4-6 hr, manual detorsion may be attempted. In 65% of cases the torsed testis rotates inward, so detorsion should be attempted in the opposite direction (e.g., the left testis is rotated clockwise). Successful manual detorsion results in dramatic pain relief.

Some adolescents experience intermittent testicular torsion. These boys report episodes of severe unilateral testicular pain that resolves spontaneously after 30-60 min. Treatment is elective bilateral scrotal orchiopexy (see Treatment).

Treatment

Treatment is prompt surgical exploration and detorsion. If the testis is explored within 6 hr of torsion, up to 90% of the gonads survive. Testicular salvage decreases rapidly with a delay of >6 hr. If the degree of torsion is 360 degrees or less, the testis might have sufficient arterial flow to allow the gonad to survive, even after 24-48 hr. Following detorsion the testis is fixed in the scrotum with nonabsorbable sutures, termed scrotal orchiopexy, to prevent torsion in the future. The contralateral testis also should be fixed in the scrotum because the predisposing anatomic condition often is bilateral. If the testis appears nonviable, orchiectomy is performed (Fig. 545-3A). Some adolescents do not undergo prompt evaluation and treatment and present with “late phase testicular torsion,” in which the spermatic cord contracts and the testis is high in the scrotum and nontender (Fig. 545-3B). Fertility is reduced in men who experience spermatic cord torsion in adolescence, irrespective of whether detorsion or orchiectomy is performed.

Spermatic cord torsion also can occur in the fetus or neonate. This condition results from incomplete attachment of the tunica vaginalis to the scrotal wall and is “extravaginal.” When torsion occurs in utero, the baby usually is born with a large, firm, nontender testis. Usually the ipsilateral hemiscrotum is ecchymotic (Fig. 545-4). In these cases, the testis rarely is viable because torsion was a remote event. However, the contralateral testis is at increased risk for torsion until 1-2 mo beyond term. The pediatric urology community is divided regarding whether immediate exploration is necessary in a male newborn who has suspected testicular torsion at birth, but if observation is recommended, the family needs to be counseled regarding the risk of contralateral spermatic cord torsion. On the other hand, if the initial exam is normal, and the newborn subsequently develops scrotal swelling and erythema, and imaging is consistent with spermatic cord torsion, emergency scrotal exploration is indicated.

TORSION OF THE APPENDIX TESTIS

Torsion of the appendix testis is the most common cause of testicular pain in boys 2-10 yr but is rare in adolescents. The appendix testis is a stalk-like structure that is a vestigial embryonic remnant of the müllerian (paramesonephric) ductal system that is attached to the upper
EPIDIDYMITIS

Acute inflammation of the epididymis is an ascending retrograde infection from the urethra, through the vas into the epididymis. This condition causes acute scrotal pain, erythema, and swelling. It is rare before puberty and should raise the question of a congenital abnormality of the wolffian duct, such as an ectopic ureter entering the vas. In younger boys, the responsible organism is often *Escherichia coli* (see Chapter 200). After puberty, bacterial epididymitis becomes progressively more common and is the principal cause of acute painful scrotal swelling in young sexually active men. Urinalysis usually reveals pyuria. Epididymitis can be infectious (usually gonococcus or *Chlamydia*; see Chapters 192 and 226), but often the organism remains undetermined. Additional etiologies include familial Mediterranean fever, enterovirus, and adenoviruses. Treatment consists of bed rest and antibiotics as indicated. Differentiation from torsion can be difficult, and surgical exploration may be required in children.

Henoch-Schönlein purpura (see Chapter 484) is a systemic vasculitis that involves multiple organ systems and that can involve the kidney and spermatic cord. When the spermatic cord is involved, typically there is bilateral painful scrotal swelling with purpuric lesions involving the scrotum. Scrotal sonography should show normal testicular blood flow. Treatment is directed toward systemic treatment of the Henoch-Schönlein purpura. Isolated testicular vasculitis is less common than that in Henoch-Schönlein purpura; polyarteritis nodosa should be suspected.

VARICOCELE

A varicocele is a congenital condition in which there is abnormal dilatation of the pampiniform plexus in the scrotum, often described as a “bag of worms” (Fig. 545-6). Dilation of the pampiniform venous plexus results from valvular incompetence of the internal spermatic vein. Approximately 15% of adult men have a varicocele; of these, approximately 10-15% are subfertile. Varicocele is the most common (and virtually the only) surgically correctable cause of subfertility in men. A varicocele is found in 5-15% of adolescent boys, but it rarely is diagnosed in boys younger than 10 yr old, because the varicocele becomes distended only after the increased blood flow associated with puberty occurs. Varicoceles occur predominantly on the left side, are bilateral in 2% of cases, and rarely involve the right side only. A varicocele in a boy younger than age 10 yr or on the right side might indicate an abdominal or retroperitoneal mass; an abdominal sonogram or CT scan should be performed in such cases.

A varicocele typically is a painless paratesticular mass. Occasionally patients describe a dull ache in the affected testis. Usually the varicocele is not apparent when the patient is supine because it is decompressed; in contrast, the varicocele becomes prominent when the patient is
HYDROCELE

Etiology

A hydrocele is an accumulation of fluid in the tunica vaginalis (Fig. 545-7). Between 1% and 2% of neonates have a hydrocele. In most cases, the hydrocele is noncommunicating (the processus vaginalis was obliterated during development). In such cases, the hydrocele fluid disappears by 1 yr of age. If there is a persistently patent processus, the hydrocele persists and becomes progressively larger during the day and is small in the morning. A rare variant of a hydrocele is the abdominocrotal hydrocele, in which there is a large, tense hydrocele that extends into the lower abdominal cavity. In some older boys, a non-communicating hydrocele can result from an inflammatory condition within the scrotum, such as testicular torsion, torsion of the appendix testis, epididymitis, or testicular tumor. The long-term risk of a communicating hydrocele is the development of an inguinal hernia. Some older boys and adolescents also develop a hydrocele. In some cases hydrocele develop acutely after an episode of scrotal trauma or epidiymoomchitis, whereas others develop more insidiously.

Diagnosis

On examination, hydroceles are smooth and nontender. Transillumination of the scrotum confirms the fluid-filled nature of the mass. It is important to palpate the testis, because some young men develop a hydrocele in association with a testis tumor. If compression of the fluid-filled mass completely reduces the hydrocele, an inguinal hernia/hydrocele is the likely diagnosis.

Treatment

Most congenital hydroceles resolve by 12 mo of age following reabsorption of the hydrocele fluid. If the hydrocele is large and tense, however, early surgical correction should be considered, because it is difficult to verify that the child does not have a hernia, and large hydroceles rarely disappear spontaneously. Hydroceles persisting beyond 12-18 mo usually are communicating and should be repaired. Surgical correction is similar to a herniorrhaphy (see Chapter 346). Through an inguinal incision, the spermatic cord is identified, the hydrocele fluid is drained, and a high ligation of the processus vaginalis is performed. If an older boy has a large hydrocele, often diagnostic laparoscopy can be performed to determine whether there is a patent processus vaginalis, and if the internal ring is closed, then the hydrocele may be corrected with a scrotal incision.

INGUINAL HERNIA

Inguinal hernia is discussed in Chapter 346.

TESTICULAR TUMOR

Testicular and paratesticular tumors can occur at any age, even in the newborn. Approximately 35% of prepubertal testis tumors are malignant; most commonly they are yolk sac tumors, although rhabdomyosarcoma and leukemia also can occur in this age group. In adolescents, 98% of painless solid testicular masses are malignant (see Chapter 503). Most manifest as a painless, hard testicular mass that does not transilluminate. Scrotal ultrasonography should be performed to confirm the finding of a testicular mass and it can help to delineate the type of testis tumor. Serum tumor markers, including α-fetoprotein and β-human

Disorders

extends into the lower abdominal cavity. In some older boys, a non-inoscrotal hydrocele, in which there is a large, tense hydrocele that is small in the morning. A rare variant of a hydrocele is the abdominocrotal hydrocele. In such cases, the hydrocele fluid is drained, and a high ligation of the processus vaginalis is performed. If an older boy has a large hydrocele, often diagnostic laparoscopy can be performed to determine whether there is a patent processus vaginalis, and if the internal ring is closed, then the hydrocele may be corrected with a scrotal incision.

Approximately 35% of prepubertal testis tumors are malignant; most commonly they are yolk sac tumors, although rhabdomyosarcoma and leukemia also can occur in this age group. In adolescents, 98% of painless solid testicular masses are malignant (see Chapter 503). Most manifest as a painless, hard testicular mass that does not transilluminate. Scrotal ultrasonography should be performed to confirm the finding of a testicular mass and it can help to delineate the type of testis tumor. Serum tumor markers, including α-fetoprotein and β-human
**chorionic gonadotropin**, should be drawn. Definitive therapy includes surgical exploration through an inguinal incision. In most cases, a radical orchiectomy, consisting of removal of the entire testis and spermatic cord, is performed. In a prepubertal boy, if the ultrasonographic study or surgical exploration suggests that the tumor is localized and benign, such as a teratoma or epidermoid cyst, testis-sparing surgery with removal only of the mass may be appropriate.

Testicular microlithiasis identified incidentally with ultrasonography may be a risk factor for future neoplasia.

ETIOLOGY
Most injuries to the genitourinary tract in children result from blunt trauma during falls, athletic activities, or motor vehicle crashes (see Chapter 72). Children are at greater risk of blunt renal injury than are adults, because they have less body fat and because the kidneys are not located directly behind the ribs. Children with a preexisting renal anomaly, such as hydronephrosis secondary to a ureteropelvic junction obstruction, horseshoe kidney, or renal ectopia, also are at increased risk for renal injury. Blunt abdominal or flank trauma often causes a renal injury. Falling can cause a deceleration injury that results in an injury to the renal pedicle, interrupting blood flow to the kidney. If the bladder is full, blunt lower abdominal trauma can cause a bladder rupture. Rupture of the membranous urethra occurs in 5% of pelvic fractures. Straddle injuries usually are associated with trauma to the bulbous urethra.

Symptoms and signs of urinary tract injury include gross or microscopic hematuria, bleeding from the urethral meatus, abdominal or flank pain, a flank mass, fractured lower ribs or lumbar transverse processes, and a perineal or scrotal hematoma.

In more than 50% of cases there also are major injuries to the brain, spinal cord, skeleton, lungs, or abdominal organs.

DIAGNOSIS
Evaluation of the patient begins after an adequate airway has been established and the patient is hemodynamically stable (see Chapter 67). With significant abdominal injury, gross hematuria or >50 red blood cells per high-power field, or suspicion of renal injury (deceleration injury, flank pain or bruise), renal imaging is indicated. The bladder should be catheterized unless blood is dripping from the urethral meatus, which is an indication of potential urethral injury. Passing the catheter in the presence of a urethral injury can increase the extent of the damage and convert a partial membranous urethral tear into a total disruption. In these patients, a retrograde urethrogram should be performed by injecting radiopaque contrast medium into the urethral meatus under fluoroscopy. Oblique radiographs demonstrate the extent of the injury and whether urethral continuity is preserved or has been disrupted.

A 3-phase spiral CT scan should be performed to evaluate the kidneys, ureters, and bladder. The delayed images are important to detect renal extravasation of blood or urine. Prompt function of both kidneys without extravasation usually excludes significant renal injury. Renal injuries are classified according to the grading scale presented in Table 546-1. Minor renal injuries are most common; these include contusion of the renal parenchyma and shallow cortical lacerations not involving the collecting system. Major renal injuries include deep lacerations involving the collecting system, the shattered kidney, and renal pedicle injuries (Fig. 546-1). Complete absence of function of 1 kidney without contralateral compensatory hypertrophy (indicating congenital absence) should be regarded as an indication of major injury to the renal pedicle. Renal angiography, once used for further evaluation of renal injuries, particularly if a renal pedicle injury is suspected, now is rarely used because such patients are often hemodynamically unstable, and management is not significantly affected by the findings. In some cases, a preexisting renal anomaly is demonstrated on the study. A ruptured ureteropelvic junction obstruction may be apparent if the kidney is intact but the distal ureter is not visualized.

If there is a pelvic fracture, a urethral transection injury should be suspected. The risk is directly related to the number of broken pubic

and whether there is separation of the pubic symphysis or displacement of the posterior pubic arch. Radiographic evaluation with retrograde urethrography should be performed if there is blood at the urethral or vaginal meatus, inability to void, and a perineal or penile hematoma.

**TREATMENT**

Minor renal injuries such as contusions are managed by bed rest and monitoring of vital signs until abdominal or flank discomfort and gross hematuria have resolved. Children with a major renal injury usually are admitted to an intensive care unit for continuous monitoring of vital signs and urine output. Intravenous antibiotics are also administered. These injuries also are managed nonoperatively, because Gerota’s fascia often causes tamponade of bleeding from the kidney, and dramatic healing of the injured parenchyma can occur even with significant urinary extravasation.

Approximately 10% of children with a major renal injury undergo surgical exploration because of hemodynamic instability, persistent extravasation, or persistent hematuria or to correct a congenital renal deformity. It can be difficult to identify normal and devitalized parenchyma, and the likelihood of having to remove the kidney is significant. If the child is undergoing exploration for other abdominal injuries, the injured kidney is examined. If there is persistent extravasation because of intermittent ureteral obstruction from a blood clot, passage of a temporary double-J stent endoscopically between the bladder and kidney might allow resolution. If the renal pedicle is injured, nephrectomy is necessary. The kidney can be salvaged by emergency renal revascularization only if the kidney is explored within 2-3 hr of the injury. Virtually all penetrating injuries of the kidneys should be explored.

In addition to loss of renal function, the main long-term complication of renal injury is renin-mediated hypertension. Children who sustain significant renal injuries should have periodic measurement of blood pressure if they have any residual renal abnormality. Ureretal injuries usually are iatrogenic. Injuries of the ureter by blunt or penetrating trauma require immediate surgical attention.

When the bladder can be catheterized, a static cystogram is obtained, infusing a contrast solution through the catheter by gravity, ideally using fluoroscopy. Flat and oblique views are often obtained; a postvoid film also should be obtained because, in some cases, extravasation may be hidden by the full bladder. Bladder ruptures can be intraperitoneal or extraperitoneal. All intraperitoneal ruptures require surgical repair. Minor extraperitoneal near-ruptures might be treated by catheter drainage but generally require surgical treatment.

Treatment of a membranous urethral injury is controversial. Erectile dysfunction, urethral stricture, and urinary incontinence are the major late complications of rupture of the membranous urethra, and therapy is directed at minimizing the risk of these problems. A large pelvic hematoma with tamponade often is present, and an immediate attempt to repair the injury can be technically difficult and result in significant hemorrhage. Many such injuries are managed initially by temporary suprapubic cystostomy, with continuous bladder drainage for 3-6 mo. Subsequently, open or endoscopic urethroplasty can be performed. Alternatively, some try to achieve urethral continuity under anesthesia and leave a urethral catheter for several months. These patients typically require subsequent open urethroplasty.

Penile injury is uncommon. A risk of newborn circumcision with a Mogen clamp is partial or complete glans amputation. With immediate surgical repair, often the excised glans tissue can be replaced as a free graft. Some boys who are in the process of toilet training sustain an injury to the glans penis if the lid of the toilet falls while they are urinating. These boys often have a hematoma covering the distal half of the glans. Typically, they have no difficulty urinating and do not need extensive evaluation. Some male infants develop an inadvertent hair coil tourniquet or strangulation injury. Typically a very narrow constriction is noted with severe distal penile swelling and pain. Identification and incision of the hair allows prompt resolution of the edema. The urethra and penile vascularity should be assessed after release of the hair coil. Adolescent boys who indulge in extremely vigorous sexual intercourse may sustain rupture of one of the corporal bodies. These boys have severe swelling of the penile shaft and require emergency exploration and repair. Boys with penetrating injuries of the penis also require emergency debridement and repair.

Testicular injuries are relatively uncommon in children because of the small size of the testes and their mobility within the scrotum. Such injuries usually result from blunt trauma during athletic activity. Typically, these boys have significant scrotal swelling, testicular pain, and tenderness (Fig. 546-2A). Ultrasonography demonstrates rupture of the tunica albuginea, which is the capsule of the testis, and surrounding hemorrhage. Prompt surgical treatment of testicular injuries increases the salvage rate (Fig. 546-2B). An uncommon injury is the zipper injury, which can affect either the scrotum or foreskin. This problem generally occurs in boys who do not wear underwear. The zipper can be cut with bone cutters or metal cutters. Sedation generally is unnecessary.

**Figure 546-2** A, Adolescent boy with blunt right testicular injury. B, Tunica albuginea of testis is ruptured; the patient underwent debridement and closure of testicular capsule.

Bibliography

Urinary lithiasis in children is related to genetic, climatic, dietary, and socioeconomic factors. The incidence is increasing; in 1996 the rate of symptomatic nephrolithiasis was 7.9 in 10,000, whereas in 2007 it was 18.5 in 10,000. Adolescents are 10 times more likely to have a symptomatic calculus compared to children 0-3 yr. The increase in stone disease in the United States is attributed to obesity and changes in dietary habits, such as increased sodium and fructose intake, and decreased calcium and water intake.

Urolithiasis is less common in the United States than in other parts of the world. Approximately 7% of urinary calculi occur in children younger than 16 yr of age. In the United States, many children with stone disease have a metabolic abnormality. The exceptions are patients with a neuropathic bladder (see Chapter 542), who are prone to infection-initiated renal stones, and those who have urinary tract reconstruction with small or large intestine, which predisposes to bladder calculi. The incidence of metabolic stones is similar in boys and girls; they are most common in southeastern United States and are uncommon in African-Americans. In Southeast Asia, urinary calculi are endemic and are related to dietary factors. Contamination of infant formula with the organic base and illegally added nitrogen-containing food additive melamine was reported in China in 2008 and is the source of much study in that country.

**STONE FORMATION**

Nearly 90% of urinary stones contain calcium as a major constituent, and 60% are composed of calcium oxalate. Most “spontaneous” stones are composed of calcium, oxalate, or phosphate crystals; others are caused by uric acid, cystine, ammonium crystals, or phosphate crystals, or a combination of these substances (Table 547-1). The risk of stone formation increases in the presence of increasing concentrations of these crystals and is reduced with increasing concentrations of urinary inhibitors. Renal calculi develop from crystals that form on the calyx and aggregate to form a calculus. Bladder calculi may be stones that formed in the kidney and traveled down the ureter, or they can form primarily in the bladder.

Low urine volume, low urine pH, calcium, sodium, oxalate, and urate are known to promote stone formation. Many inorganic (e.g., citrate, magnesium) and organic (e.g., glycosaminoglycans, osteopontin) substances are known to inhibit stone formation. Organic inhibitory compounds adsorb to the surface of the crystal, thereby inhibiting crystal growth and nucleation.

Stone formation depends on 4 factors: matrix, precipitation–crystallization, epitaxy, and the absence of inhibitors of stone formation in the urine. **Matrix** is a mixture of protein, nonamino sugars, glucosamine, water, and organic ash that makes up 2-9% of the dry weight of urinary stones and is arranged within the stones in organized concentric laminations. **Precipitation–crystallization** refers to supersaturation of the urine with specific ions composing the crystal. Crystals aggregate by chemical and electrical forces. Increasing the saturation of urine with respect to the ions increases the rate of nucleation, crystal growth, and aggregation and increases the likelihood of stone formation and growth. **Epitaxy** refers to the aggregation of crystals of different composition but similar lattice structure, thus forming stones of a heterogeneous nature. The lattice structures of calcium oxalate and monosodium urate have similar structures, and calcium oxalate crystals can aggregate on a nucleus of monosodium urate crystals. Urine also contains inhibitors of stone formation, including citrate, diphosphonate, and magnesium ion.

**CLINICAL MANIFESTATIONS**

Children with urolithiasis usually have gross or microscopic hematuria. If the calculus causes obstruction, then severe flank pain (renal colic) or abdominal pain occurs. The calculus typically causes obstruction at areas of narrowing of the urinary tract—the ureteropelvic junction, where the ureter crosses the iliac vessels, and the ureterovesical junction. The ureter progressively narrows distally, and its most narrow segment is the ureterovesical junction. Typically the pain radiates anteriorly to the scrotum or labia. Often the pain is intermittent, corresponding to periods of obstruction of urine flow, which increases the pressure in the collecting system. If the calculus is in the distal ureter, the child can have irritative symptoms of dysuria, urgency, and frequency. If the stone passes into the bladder, the child usually is asymptomatic. If the stone is in the urethra, dysuria and difficulty voiding can result, particularly in boys. Some children pass small amounts of gravel-like material. Stones can also be asymptomatic, although it is uncommon to pass a ureteral calculus without symptoms.

**DIAGNOSIS**

Approximately 90% of urinary calculi are calcified to some degree and consequently are radiopaque on a plain abdominal film. However, many calculi are only a few millimeters in diameter and are difficult to
see, particularly if they are in the ureter. Struvite (magnesium ammonium phosphate) stones are radiopaque. Cystine, xanthine, and uric acid calculi may be radiolucent but often are slightly opacified. Some children have nephrocalcinosis, which is calcification of the renal tissue itself. Nephrocalcinosis is seen most commonly in premature neonates receiving furosemide, which causes hypercalcemia, and in children with medullary sponge kidney.

In a child with suspected renal colic, there are multiple imaging options. The most accurate study is an unenhanced spiral CT scan of the abdomen and pelvis (Fig. 547-1). This study takes only a few minutes to perform, has 96% sensitivity and specificity in delineating the number and location of calculi, and demonstrates whether the involved kidney is hydronephrotic. However, the radiation exposure is high. An alternative is to obtain a plain radiograph of the abdomen and pelvis plus a renal ultrasonogram. These studies can demonstrate hydronephrosis and possibly the calculus on the radiograph; however, the calculus is not visualized on sonography unless it is adjacent to the bladder. In addition, renal calculi <3 mm typically are not seen. Consequently, the clinician needs to carefully balance the risks of CT imaging against the lower sensitivity of the plain abdominal film plus sonography.

In 2008 the Society for Pediatric Radiology initiated the Image Gently initiative to educate providers on the risks of radiologic imaging in children and to encourage the use of limited imaging in children, particularly those with suspected urolithiasis (http://www.pedrad.org/associations/5364/). In a child with an already-diagnosed calculus, serial plain x-rays or renal ultrasonography can be used to follow the status of the calculus, such as whether it has grown or diminished in size or has moved. If a child has a renal pelvic calculus, a ureteropelvic junction obstruction should be suspected. In some cases, it can be difficult to determine whether hydronephrosis in such a child is secondary to an obstructing stone, ureteropelvic junction obstruction, or both.

Any material that resembles a calculus should be sent for analysis by a laboratory that specializes in identifying the components of urinary calculi.

**METABOLIC EVALUATION**

A metabolic evaluation for the most common predisposing factors should be undertaken in all children with urolithiasis, bearing in mind that structural, infectious, and metabolic factors often coexist. This evaluation should not be undertaken in a child who is in the process of passing a stone, because the altered diet and hydration status, as well as the effect of obstruction on the kidney, can alter the results of the study. Table 547-2 lists the basic laboratory studies required, and Table 547-3 shows the normal values for 24-hr urine collections. In children with hypercalciuria, further studies of calcium excretion with dietary calcium restriction and calcium loading are necessary.

**PATHOGENESIS OF SPECIFIC RENAL CALCULI**

**Calcium Oxalate and Calcium Phosphate Calculi**

Most urinary calculi in children in the United States are composed of calcium oxalate and/or calcium phosphate. The most common metabolic abnormality in these patients is normocalcemic hypercalciuria. Between 30% and 60% of children with calcium stones have hypercalciuria without hypercalcemia. Other metabolic aberrations that predispose to stone disease include hyperoxaluria, hyperuricosuria, hypocitruria, heterozygous cystinuria, hypomagnesuria, hyperparathyroidism, and renal tubular acidosis (see Chapter 529).

**Hypercalciuria** may be absorptive, renal, or resorptive. The primary disturbance in absorptive hypercalciuria is intestinal hyperabsorption of calcium. In some children, an increase in 1,25-dihydroxyvitamin D is associated with the increased calcium absorption, whereas in others the process is independent of vitamin D. Renal hypercalciuria refers to impaired renal tubular reabsorption of calcium (see Chapter 519.8). Renal leak of calcium causes mild hypocalcemia, which triggers an increased production of parathyroid hormone, with increased intestinal absorption of calcium and increased mobilization of calcium stores. Resorptive hypercalciuria is uncommon and is found in patients with primary hyperparathyroidism. Excess parathyroid hormone secretion stimulates intestinal absorption of calcium and mobilization of calcium stores. Table 547-4 summarizes the metabolic evaluation of children with hypercalciuria.

**Hyperoxaluria** is another potentially important cause of calcium stones. Oxalate increases the solubility product of calcium oxalate crystallization 7-10 times more than calcium. Consequently, hyperoxaluria significantly increases the likelihood of calcium oxalate precipitation. Oxalate is found in high concentration in tea, coffee, spinach, and rhubarb. Primary hyperoxaluria is a rare autosomal recessive disorder that can be subclassified into glycolic aciduria and L-glyceric aciduria. Most patients with primary hyperoxaluria have glycolic aciduria; oxalic and glycolic acids are increased in the urine of affected persons. Both defects cause increased endogenous production of oxalate, with hyperoxaluria, urolithiasis, nephrocalcinosis, and injury to the kidneys. Death from renal failure occurs by age 20 yr in untreated patients. Oxalosis, defined as extrarenal deposition of calcium oxalate, occurs when renal insufficiency is present with elevated plasma oxalate. Calcium oxalate deposits appear first in blood vessels and bone marrow, and with time they appear throughout the body. Secondary hyperoxaluria is more common and can occur in patients with increased intake of oxalate and oxalate precursors such as vitamin C, in those with pyridoxine deficiency, and in children with intestinal malabsorption.

**Enteric hyperoxaluria** refers to disorders such as inflammatory bowel disease (see Chapter 336), pancreatic insufficiency (see Chapter 350), and biliary disease (see Chapter 356), in which there is gastrointestinal malabsorption of fatty acids, which bind intraluminal calcium and form salts that are excreted in the feces. Normally, calcium forms a complex with oxalate to reduce oxalate absorption, but if calcium is unavailable, there is increased absorption of unbound oxalate.
Hypocitraturia refers to a low excretion of citrate, which is an important inhibitor of calcium stone formation. Citrate acts as an inhibitor of calcium urolithiasis by forming complexes with calcium, increasing the solubility of calcium in the urine, and inhibiting the aggregation of calcium phosphate and calcium oxalate crystals. Disorders such as chronic diarrhea, intestinal malabsorption, and renal tubular acidosis (see below) can cause hypocitraturia. It may also be idiopathic.

Renal tubular acidosis (RTA) is a syndrome involving a disturbance of acid–base balance within the kidney that can be classified into 3 types, one of which predisposes to renal calculi that typically are calcium phosphate (see Chapter 529). In type 1 RTA, the distal nephron does not secrete hydrogen ion into the distal tubule. The urine pH is never <5.8, and hyperchloremic hypokalemic acidosis results. Patients acquire nephrolithiasis, nephrocalcinosis, muscle weakness, and osteomalacia. Type 1 RTA can be an autosomal dominant disorder, but more often it is acquired and associated with systemic diseases such as Sjögren syndrome, Wilson disease, primary biliary cirrhosis, and lymphocytic thyroiditis, or it results from amphotericin B, lithium, or toluene (an organic solvent associated with glue sniffing).

From 5–8% of patients with cystic fibrosis (see Chapter 403) have urolithiasis. Typically the stones are calcium, and they often become manifest in adolescence or young adulthood. Microscopic nephrocalcinosis also occurs in younger children with the disease. These patients do not have hypercalciuria, and the propensity for urolithiasis has been speculated to result from an inability to excrete a sodium chloride load or from intestinal malabsorption.

Other disorders can play a role in causing calcium stones. Hyperuricosuria may be related to the epitactic growth of calcium oxalate crystals around a nucleus of uric acid crystals or to the action of uric acid as a counter inhibitor of urinary mucopolysaccharides, which inhibit calcium oxalate crystallization. Heterozygous cystinuria is found in some patients with calcium stones. The mechanism is unknown but may be similar to that of uric acid. Sarcoidosis (see Chapter 165) causes an increased sensitivity to vitamin D3 and thus an increased absorption of calcium from the gastrointestinal tract. In Lesch-Nyhan syndrome (see Chapter 89), there is excessive uric acid synthesis. These patients are more likely to form uric acid stones, but some of these stones may be calcified. Immobility can cause hypercalciuria by mobilization of calcium stores. High-dose corticosteroids can cause hypercalcemia and calcium oxalate precipitation. Furosemide, which is administered in the neonatal intensive care unit, also can cause severe hypercalcemia, urolithiasis, and nephrocalcinosis.

In some children, calcium calculi are idiopathic. A complete metabolic evaluation must be performed before this diagnosis is made.

### Cystine Calculi
Cystinuria accounts for 1% of renal calculi in children. The condition is a rare autosomal recessive disorder of the epithelial cells of the renal tubule that prevents absorption of the 4 dibasic amino acids (cystine, ornithine, arginine, lysine) and results in excessive urinary excretion of these products. The only known complication of this familial disease is the formation of calculi, because of the low solubility of cystine. The patients usually have acidic urine, which leads to a higher rate of

of indinavir-based monohydrate, although calcium oxalate and/or phosphate have been present in some. After each dose, 12% of the drug is excreted unchanged in the urine. The urine in these patients often contains crystals of characteristic rectangles and fan-shaped or starburst crystals. Indinavir is soluble at a pH of <5.5. Consequently, dissolution therapy by urinary acidification with ammonium chloride or ascorbic acid should be considered.

**Nephrocalcinosis**

Nephrocalcinosis refers to calcium deposition within the renal tissue. Often nephrocalcinosis is associated with urolithiasis. The most common causes are furosemide (administered to premature neonates), distal RTA, hyperparathyroidism, medullary sponge kidney, hypophosphatemic rickets, sarcoidosis, cortical necrosis, hyperoxaluria, prolonged immobilization, Cushing syndrome, hyperuricosuria, monogenetic causes of hypertension, and renal candidiasis.

**TREATMENT**

In a child with a renal or ureteral calculus, the decision whether to remove the stone depends on its location, size, and composition (if known) and whether obstruction and/or infection is present. Pain is managed with nonsteroidal antiinflammatory drugs or opiates. Small ureteral calculi often pass spontaneously, although the child might experience severe renal colic. The narrowest segment of the ureter is the ureterovesical junction. α-Adrenergic blockers, such as tamsulosin, terazosin, and doxazosin, facilitate stone passage in children and adults by decreasing ureteral pressure below the stone and decreasing the frequency of the peristaltic contractions of the obstructed ureter. In many cases, passage of a ureteral stent past the stone endoscopically relieves pain and dilates the ureter sufficiently to allow the calculus to pass. In cases such as children with a uric acid calculus or an infant with a furosemide-associated calculus, dissolution alkaline therapy may be effective.

If the calculus does not pass or seems unlikely to pass or if there is associated urinary tract infection, removal is necessary (Table 547-5).

A daily fluid intake of 2–2.5 L in adolescent stone formers is recommended, with greater intake during summer months.

Dietary sodium intake in children has increased significantly, up to 6.8 g/day as a consequence of increased consumption of salty, processed foods. High sodium intake increases urinary excretion of calcium and may result in hypocitraturia. In addition, increased salt intake induces metabolic acidosis. To compensate for the acid load, the kidneys conserve anions, including urinary citrate, which contributes to hypocitraturia. Reduction in dietary intake of sodium and increased potassium intake is indicated.

Although counterintuitive, low-calcium diets are less effective in the treatment of calcium stones than diets containing normal amounts of calcium and limited amounts of sodium and animal protein. Low-sodium, low-protein diets reduce urinary calcium and oxalate excretion. Children with stone disease should avoid excess calcium intake. However, children require calcium for bone development and recommendations for daily calcium intake vary by age. Consequently, calcium restriction in children should be avoided. Thiazide diuretics also reduce renal calcium excretion. Addition of potassium citrate, an inhibitor of calcium stones, with a dosage of 1–2 mEq/kg/24 hr is beneficial. An excellent source of citrate is lemonade, because 4 oz of lemon juice contains 84 mEq of citric acid. A daily mixture of 4 oz of reconstituted lemon juice in 2 L of water and sweetened to taste should significantly increase the urinary citrate level. In difficult cases, neutral orthophosphate should be given also, although it is poorly tolerated.

In patients with uric acid stones, allopurinol is effective. Allopurinol is an inhibitor of xanthine oxidase and is effective in reducing the production of both uric acid and 2,8-dihydroxyadenine and can help control recurrence of both types of stones. In addition, urinary alkalinization with sodium bicarbonate or sodium citrate is beneficial. The urine pH should be ≥6.5 and can be monitored at home by the family.

Maintaining a high urine pH can also prevent recurrence of cystine calculi. Cystine is much more soluble when the urinary pH is >7.5, and alkalinization of urine with sodium bicarbonate or sodium citrate is effective. Another important medication is D-penicillamine, which is a chelating agent that binds to cysteine or homocysteine, increasing the solubility of the product. Although poorly tolerated by many patients, it has been reported to be effective in dissolving cystine stones and in preventing recurrences when hydration and urinary alkalinization fail. N-Acetylcysteine appears to have low toxicity and may be effective in controlling cystinuria, but long-term experience with it is lacking.

Treatment of type 1 RTA involves correcting the metabolic acidosis and replacing lost potassium and sodium. Sodium or potassium citrate therapy, or both, is necessary. When the metabolic acidosis is corrected, the urinary citrate excretion returns to normal.

Treatment of primary hyperoxaluria involves liver transplantation because the defective enzymes are hepatic. Ideally, this procedure is performed before renal failure occurs. In the most severe cases, kidney transplantation is also necessary.

**HISTORY**

The approach to both the history and physical examination of a child is often a collaborative effort that involves the child, her caregiver, and the provider. With a preverbal or very young patient, clinicians obtain the majority of the history from a parent or caregiver. Even for the very young patient, developmentally appropriate social questions directed to the patient can put her at ease and help to develop cooperation and rapport that will facilitate a subsequent examination. Specific patient, caregiver, or provider concerns about vaginal discharge or bleeding, pruritus, external genital lesions or abnormalities should direct a problem-focused history. In a patient presenting with vaginal bleeding, questions should focus on recent growth and development, signs of pubertal progression, trauma, vaginal discharge, medication exposure, and any history of foreign objects in the vagina. For complaints of vulvovaginal irritation, pruritus, or discharge, questions should concentrate on perineal hygiene, the onset and duration of symptoms, the presence and quality of discharge, exposure to skin irritants, recent antibiotic use, travel, presence of medical comorbidities or infections in the patient and her family members, and other systemic symptoms of illness or skin conditions. Throughout the history, the patient should be encouraged to ask her own questions. Occasionally, the child is brought to the clinician because she or her parents have concerns about anatomic findings, developmental changes, or congenital anomalies. It helps to understand the family’s concerns and if a specific reason, event, or family history raised the need for a gynecologic consultation.

**GYNECOLOGIC EXAMINATION**

The physical examination of the patient should be tailored to the child’s age, complaint, and any other concerns elicited in the history. The menstrual period should be included with an assessment of other vital signs as age appropriate.

**Neonates**

The delivering obstetrician should briefly examine the external genitals of female infants to confirm the patency of the vagina and assess the presence of any obvious genital anomalies. The pediatrician’s newborn examination should note any abnormal findings such as ambiguous genitalia, imperforate hymen, urogenital abnormalities, abdominal mass, or inguinal hernia that might herald a gynecologic problem.

Placing the infant in the supine position with thighs flexed against the abdomen allows visualization of the neonate’s external genitals. Estrogenic effects commonly notable in neonates include prominence of the labia majora and a white vaginal discharge. The labia minora and hymen may protrude slightly from the vestibule. A small amount of neonatal vaginal bleeding from endometrial sloughing following maternal hormone withdrawal might occur. Bleeding that is excessive or persistent beyond 1 mo of life requires further evaluation. Breast buds may be palpable at the time of the neonatal examination but should regress in the 1st mo of life; occasionally, nipple discharge occurs.

The vaginal orifice may be difficult to see. Gentle lateral traction on the labia majora usually allows complete visualization of the hymen and vaginal orifice. The hymen should be evaluated for patency. Most hymenal variations—imperforate, microperforate, septate—do not require treatment during the neonatal period. Variations should be noted and readressed in subsequent visits. The hymen originates from the urogenital sinus. The uterus and vagina originate from the müllerian ducts. The concomitant renal malformations seen with müllerian anomalies are not associated with hymenal anomalies. Hymenal polyps seen in newborns typically regress in size as the maternal estrogen effects subside. Cervicovaginal mucus secretions can accumulate behind the blocked outflow tract of an imperforate hymen and manifest as a mucocolpos. *In this instance, correction of the imperforate hymen in the neonatal period is indicated if urinary obstruction occurs.*

The clitoris may appear large in proportion to the other genital structures, especially in premature infants. If the clitoris appears enlarged, the clitoral width should be measured; values >6 mm in a newborn indicate a need for further evaluation. *If clitoromegaly and ambiguous genitals are present, the obstetrician and pediatrician should immediately obtain expert consultation for evaluation of the infant and to counsel the parents.* Congenital adrenal hyperplasia is the most common cause of ambiguous genitals (accounting for more than 90% of cases), and the salt-wasting forms can lead to rapid dehydration with subsequent fluid and electrolyte imbalance (see Chapter 576). Delay in the diagnosis and treatment of congenital adrenal hyperplasia may be life-threatening.

In the neonate, the ovaries are <1 cm in diameter and average 1 cm³ in volume. Antenatal or postnatal abdominopelvic ultrasound might reveal small simple ovarian cysts, which represent normal follicles. Because of the abdominal location of ovaries in the neonate, ovarian enlargement can manifest as a palpable abdominal mass. Large cysts (>4–5 cm) or those of a complex nature pose the risk of ovarian torsion, hemorrhage into the cyst, or, uncommonly, an ovarian tumor. A non-resolving or enlarging neonatal ovarian cyst warrants expert consultation. If the mass causes respiratory compromise or gastrointestinal obstruction, decompression is usually performed. Cyst aspiration can give temporary relief, but it is not recommended as the fluid aspirated is not reliable for diagnosis and fluid may reaccumulate. If a cystectomy is done for appropriate clinical indications the cyst wall should be surgically excised to prevent reaccumulation of fluid and to provide a pathologic diagnosis, the remaining ovarian tissue should be left in situ, and the contralateral ovary should be inspected. Preservation of normal ovarian tissue is recommended for all benign lesions, and salpingo-oophorectomy should not be performed unless clinically indicated.

**Infants and Prepubertal Girls**

As the maternal estrogen effect subsides, the genitals of the female infant change in appearance. The labia begin to flatten. The hymenal membrane loses its redundancy and becomes translucent. The hypoes- trogenic prepubertal vaginal epithelium appears thin, red, and sensitive to the touch. The vaginal mucosa of young children can have longitudinal ridges running along the axis of the vagina at 3 o’clock, 6 o’clock, and 9 o’clock, which can cause small protrusions on the hymen at these locations. The cervix usually appears flat and flush with the vaginal vault. During infancy, the uterus regresses in size and does not return to its birth size until the 5th or 6th year. The prepubertal cervix: fundus ratio is 2:1.
As puberty approaches, the child experiences increasing endocrine activity of the hypothalamus, pituitary gland, adrenal gland, and ovaries (see Chapter 561). The labia majora begin to fill out, and the labia minora thicken and elongate as a result of increased estrogen levels. The hymen thickens and becomes more redundant. Clear or white physiologic secretions may be present. Breast buds begin to appear, either bilateral or initially unilateral with subsequent development of the contralateral breast.

**Indications for Genital Examination**

Genitourinary complaints or suspected genitourinary pathology warrant assessment of the external and internal genitals of pediatric patients, specifically in cases of vaginal bleeding, vaginal discharge, vulvar trauma, presence of a foreign body, perineal or pelvic masses, vulvovaginal ulcerative or inflammatory lesions, congenital anomalies, or suspected sexual abuse.

**Preparation**

The genital examination in prepubertal girls requires a gentle, patient approach to maximize cooperation and minimize fear and embarrassment. A clear, simple explanation of what the exam involves can facilitate the child's comfort and cooperation. The presence of a parent or caregiver during the entire examination provides reassurance for most children. For the older prepubertal patient, the physician may discuss whether the patient wishes to have a family member present during the examination. Even in the presence of the caregiver, the examiner should speak directly to the child. Prior to initiating any part of the examination, the provider should explicitly verify with both the patient and her caregiver that the caregiver has given permission for the examination. This provides an opportunity to explain to the child the privacy of body parts and who may examine or touch those areas. It is useful to educate the patient and caregiver about the basic anatomy and hygiene of the external genital area. Before each step of the examination, the physician should explain what will occur. Allowing an older child the option of watching her examination with a handheld mirror may contribute to her comfort and understanding. Forcible restraint is never indicated; if optimal evaluation is not possible, the clinician must assess the acuity of the complaint and pathology and determine the potential need for a multi-visit examination or an examination under anesthesia.

**Positioning**

A variety of techniques and positions can facilitate the genital examination in prepubertal patients. Children younger than 4 yr of age can be placed on the parent or caregiver's lap with the child's legs straddling the parent's thighs. If the child permits, she may be positioned on the table in the supine position with the hips fully abducted and the feet together in the frogleg (diamond or butterfly) position. Older children may prefer to use the stirrups. The head of the examination table should be raised so that eye contact can be maintained with the patient throughout the examination. When the child is supine, grasping the labia majora along the inferior portion between the thumb and index finger and gently pulling outward and posteriorly (labial traction) allows visualization of the vaginal introitus. Alternatively, the child may be placed in the knee–chest position with elevation of the buttocks and hips. This position provides exposure of the inferior portion of the hymen, the lower vagina, and possibly the upper vagina and cervix but has the disadvantage of having the child face away from the examiner.

Some extremely cooperative children tolerate a vaginoscopic examination in an outpatient office setting for better intravaginal assessment. The endoscope (either a cystoscope or a hysteroscope) is placed in the vagina and the labia are gently opposed, allowing the vagina to distend with water. This technique permits visualization of the vagina and cervix, allowing for the evaluation of an injury, lesion, and anatomic variant or for the presence of a foreign body. Application of 2% lidocaine gel at the introitus makes the insertion easier and less irritating for the patient. If a more complete examination is indicated or if the child is too young, frightened or unable to cooperate, an examination under anesthesia is recommended.

**Documentation**

Clinicians should thoroughly and accurately document genital exam findings in the medical record, reserving conclusions and diagnostic terms for the impression and plan portion of the documentation rather than in the description of exam findings. Each structure visualized should be noted (e.g., clitoris, labia majora, labia minora, urethra, vestibule, and rectum) with attention to describing normal appearance and any anatomic variations (e.g., the configuration of the hymen as annular, crescentic, etc.). Describing any findings or lesions using a clock-face method provides a consistent reference point; a sketch or magnified photograph may also be helpful. Future examiners will rely on this documentation as a record with which they compare their findings and note any variances. Changes should be noted in any follow-up examinations.

**Adolescents**

Some teens prefer to initially meet and discuss the reason for their visit with the provider without their parent or guardian present, and this request should be honored (see Chapter 112). A majority of the time, obtaining a history from an adolescent begins with meeting the patient and her parent or caregiver together to review her history and the reason for the visit and to explain the concepts of confidentiality and privacy. Familiarity with local laws governing limitations to confidential services should guide the protection of the adolescent and her parents' rights to information access and privacy. The Guttmacher Institute provides an up-to-date listing of state and federal laws in the United States affecting access to medical care (http://www.guttmacher.org/statecenter/spibs/index.html). Brief discussions of normal pubertal development and menstruation can reassure both patients and their parents or guardians and provide valuable education on appropriate menstrual flow, menstrual hygiene and the duration and frequency of bleeding. Introducing the menstrual diary as an invaluable tool for the teen can help patients, parents, and clinicians identify abnormal bleeding patterns that might require further evaluation. Many apps are available for tracking menstrual periods on a smartphone or computer.

After the initial interview with the teen and her parent or caregiver, the confidential and sensitive portion of the history, particularly sexual history and alcohol, tobacco, and drug use, is taken with the teen alone. Such a request could be phrased as follows: “I would like to give your daughter an opportunity to ask any questions she might have privately, so would you mind stepping out of the room for a moment?” Concerns for the presence of vaginal discharge, the potential for sexually transmitted infections, pregnancy, or menstrual aberration should be explored. Teens and their parents should be informed of the proper use and accessibility of condoms, all contraceptive methods, and emergency contraception.

A number of resources for educating adolescents regarding their first pelvic examination and in-depth sexual history and psychosocial screening tools are available. These include the North American Society for Pediatric and Adolescent Gynecology (http://www.naspag.org), the American Academy of Pediatrics (http://www.aap.org), the Society for Adolescent Health and Medicine (http://www.adolescenthealth.org), and the American College of Obstetricians and Gynecologists (http://acog.org/Patients).

**Pelvic Examination**

Table 548-1 presents the indications for the first pelvic examination in adolescents: age older than 12 yr, abnormal uterine bleeding, vulvovaginitis, severe dysmenorrhea, unexplained dysuria or abdominal pain, evaluation and removal of a foreign body, and placement of an intrauterine device. If an adolescent does not meet 1 of the criteria
Before touching the introitus, it may be useful to touch the inner thigh with the speculum. Compression of the urethra anteriorly should be avoided. Gentle pressure with a finger for displacement of the fourchette posteriorly further facilitates proper speculum placement. After visualization of the vagina and cervix, specimens should be obtained as indicated. A bimanual examination, sometimes with a single digit, allows palpation of the vaginal walls and cervix and bimanual assessment of the uterus and adnexa. Reassurance of normal findings throughout the examination should be provided, and normal variants to anatomy should be pointed out to the teen as they are encountered (e.g., asymmetric labia minora).

Following the examination, it is appropriate to review the exam findings with the teen (and her parent) and initiate a collaborative discussion of the management plan. Encouraging the adolescent to participate in decision making empowers her to undertake responsibility for her health, may strengthen compliance with the medical plan, and acknowledge her as a unique individual.

Bibliography is available at Expert Consult.

listed in Table 548-1, the American College of Obstetricians and Gynecologists recommends that the first gynecologic encounter occur between the ages of 13 and 15 yr (Table 548-2) with attention toward anticipatory guidance focusing on normal pubertal development and menstruation. Patients should undergo screening for sexually transmitted infection with each new sexual partner. With the availability of urine and vaginal swab nucleic acid amplification testing for chlamydia and gonorrhea, sexually transmitted infection screening does not necessitate a speculum exam.

Prior to the initiation of a physical examination, all young women should be offered the choice of having a medical attendant, family member, or friend present during her examination. At the initial gynecologic exam, the physician should explain the process in understandable terms. A thorough evaluation begins with an assessment of body mass index, blood pressure, menstruation status, thyroid, lymph nodes, breast development, abdominal exam, and skin. The external genitals should be examined with the patient in the dorsal lithotomy position while communication is maintained between the physician and patient. Elevating the head of the examination table allows the teen and her examiner to maintain eye contact. The teen can hold a mirror to follow along with the examination, and she should be encouraged to ask questions. Inspection of the vulva is followed by inspection of the Bartholin, urethral, and Skene glands. The clitoris, normally 2-4 mm in width, is then assessed; a clitoris wider than 10 mm, especially in the presence of other signs of virilization, suggests a need for further evaluation. The hymenal anatomy should also be evaluated. Throughout the examination, the proper nomenclature for genital anatomy should be emphasized with the teen to empower her to use proper wordage with the avoidance of slang when referring to her body.

Because the initial Papanicolaou test is deferred until 21 yr of age and cultures for sexually transmitted infections can be obtained from urine or vaginal swabs, the need for a speculum exam is decreasing in this age group. If a speculum exam is indicated, use an appropriate sized speculum, such as the Huffman \((\frac{1}{2} \text{ in wide} \times 4 \text{ in long})\) or Pedersen \((\frac{3}{4} \text{ in wide} \times 4 \text{ in long})\). Shorter speculums will not allow visualization of the entire vaginal canal. The adolescent patient should be reassured that the exam may be uncomfortable but should not be painful and that her request to stop or wait will be honored. Encouraging the patient to watch with a hand-held mirror facilitates patient education and can be empowering. She may be told before the insertion of the speculum that she will experience a pressure sensation.
Bibliography

Committee on Adolescent Health Care: Tool kit for teen care, ed 2, Atlanta, 2009, American College of Obstetrician and Gynecologists.

Vulvovaginitis, the most common gynecologic-based problem for prepubertal children, is typically caused by either inadequate or excessive hygiene or chemical irritants. The condition is usually improved by hygiene measures and education of the caregivers and child.

**ETIOLOGY**

Vulvitis refers to external genital pruritus, burning, redness, or rash. Vaginitis implies inflammation of the vagina, which can manifest as a discharge with or without an odor or bleeding. These may occur simultaneously as vulvovaginitis. When a child presents with vulvovaginitis, the history should include questions on hygiene (wiping from front to back) and information about possible chemical irritants (bath soaps, laundry detergents, swimming pools, or hot tubs). The caregiver can be asked about a history of diarrhea, perianal itching, or nighttime itching. The possibility of foreign objects being placed into the vagina should also be asked, although the young child is unlikely to remember or recall. Children are especially prone to nonspecific vulvovaginitis for a variety of reasons, including their nonestrogenized state, poor perianal hygiene, and the proximity of the anus to the vagina, which is without geographic barriers given the flattened labia and lack of pubic hair (Fig. 549-1 and Table 549-1).

**EPIDEMIOLOGY**

Infectious vulvovaginitis, where a specific pathogen is isolated as the cause of symptoms, may be caused by fecal or respiratory pathogens and cultures might reveal *Escherichia coli* (see Chapter 200), *Streptococcus pyogenes*, *Staphylococcus aureus* (see Chapter 181), *Haemophilus influenzae* (see Chapter 194), *Enterobius vermicularis*, and, rarely, *Candida* spp. (see Chapter 234). These organisms may be transmitted by the child using improper toilet hygiene and manually from the nasopharynx to the vagina. The children present with perianal redness, an inflamed introitus, and often a yellow-green or mildly bloody discharge. They may be observed to be grabbing their genital area or “digging” in their underwear, which is usually stained with yellow-brown discharge. Attempts to treat these bacterial etiologies with antifungal medication will fail and often the antifungal product will lead to more irritation. Table 549-2 gives specific treatment recommendations based on the bacteria localized.
**Neisseria gonorrhoeae** or *Chlamydia trachomatis* also are causes of specific infectious vulvovaginitis (see Chapter 120). Management of children who have sexually transmitted infections requires close cooperation between clinicians and child-protection authorities. Official investigations for sexual abuse, when indicated, should be initiated promptly (see Chapter 40). If acquired after the neonatal period, some diseases (e.g., gonorrhea, syphilis, and chlamydia) are virtually 100% indicative of sexual contact. For other diseases (e.g., human papillomavirus infection and herpes simplex virus), the association with sexual contact is not as clear. Presumptive treatment for children who have been sexually assaulted or abused is not recommended because (1) the incidence of most sexually transmitted infections in children is low after abuse/assault, (2) prepupertal girls appear to be at lower risk for ascending infection than adolescent or adult women, and (3) regular follow-up of children usually can be ensured. Although *Trichomonas vaginalis* can be transmitted vertically and can be seen in children up to 1 yr of age, it is an uncommon cause of specific infectious vulvovaginitis in the unestrogenized prepubertal girl.

Other causes of specific infectious vulvovaginitis include *Shigella* (see Chapter 199), which often manifests with a blood-tinged purulent discharge, and *Yersinia enterocolitica* (see Chapter 203). *Candida* infections (yeast) commonly cause diaper rash, but they are unlikely to cause vaginitis in children because the alkaline pH of the prepubertal vagina does not support fungal infections. Exceptions can occur in diabetic or immunocompromised children or children on prolonged antibiotics. Pinworms are the most common helminthic infestation in the United States, with the highest rates in school-age and preschool children. Perianal itching can lead to excoriation and, rarely, bleeding.

## CLINICAL MANIFESTATIONS

### Diaper Dermatitis

Diaper dermatitis is the most common dermatologic problem in infancy and occurs in half of all diaper-wearing infants and children. The moisture and contact with urine and feces irritates the skin, and colonization with *Candida* spp. increases the severity of the dermatitis. First-line treatment includes hygiene measures such as increasing the frequency of diaper changes, allowing the infant to be diaper free, Figure 549-1 Labial adhesions. (Photo courtesy of Diane F. Merritt, MD.)

<th>TREATMENT</th>
</tr>
</thead>
<tbody>
<tr>
<td>Molluscum contagiosum <em>(Fig. 549-7)</em></td>
<td>1-5 mm discrete, skin-colored, dome-shaped, umbilicated lesions with a central cheesy plug</td>
<td>Diagnosis usually is made by visual inspection</td>
<td>The disease generally is self-limited and the lesions can resolve spontaneously. Treatment choices in children may include cryosurgery, laser, application of topical anesthetic and curettage, podophyllotoxin, and topical silver nitrate. Use of topical 5% imiquimod cream and 10% potassium hydroxide has been reported with similar effects.</td>
</tr>
<tr>
<td>Condyloma acuminata</td>
<td>Skin-colored papules, some with a shaggy, cauliflower-like appearance</td>
<td>Diagnosis usually is made by visual inspection. Biopsy should be reserved for when the diagnosis is in question. Human papillomavirus DNA testing is not helpful</td>
<td>Many lesions in children resolve spontaneously, “wait and see” often utilized in children (60 days). Topical treatment with imiquimod cream and podophyllotoxin is the most studied (daily qhs 3 times/wk x 16 wk, wash 6-10 hr after application). General anesthesia is usually required for surgical/ablative procedures (cryotherapy, laser therapy, electrocautery)–reserve for symptomatic or large lesions. Other treatments have been utilized in adults, including trichloroacetic acid, 5-fluorouracil, sinecatechins, topical cidofovir, and cimetidine. The efficacy and safety of these treatments in children has not been established.</td>
</tr>
<tr>
<td>Herpes simplex</td>
<td>Blister that break, leaving tender ulcers</td>
<td>Visual inspection confirmed by culture from lesion</td>
<td>Infants: Acyclovir 20 mg/kg body weight IV q8 hr × 21 days for disseminated and central nervous system disease or × 14 days for disease limited to the skin and mucous membranes. Genital/mucocutaneous disease: Age 3 mo–2 yr: 15 mg/kg/day IV divided in q8h × 5-7 days. Age 2-12 yr (1st episode): Same as above or 1,200 mg/day divided in q8h dosing × 7-10 days. Age 2-12 yr (Reoccurrence): 1,200 mg/day in q8h dosing or 1,600 mg/day in bid dosing × 5 days (give 3-5 days for children older than 12 yr).</td>

<tr>
<td>----------</td>
<td>--------------</td>
<td>-----------</td>
<td>----------</td>
</tr>
<tr>
<td>Labial agglutination (see Fig. 549-1)</td>
<td>May be asymptomatic or can cause vulvitis, urinary dribbling, urinary tract infection, or urethritis</td>
<td>Diagnosis is made by visual inspection of the adherent labia, often with a central semitranslucent line</td>
<td>Does not require treatment if the patient is asymptomatic. Symptomatic patients: Topical estrogen cream or betamethasone ointment applied alone or in combination daily for 6 wk directly to the line of adhesion, using a cotton swab while applying gentle labial traction. Estrogen should be interrupted if breast budding occurs. Mechanical or surgical separation of the adhesions is rarely indicated. The adhesions usually resolve in 6-12 wk; unless good hygiene measures are followed, reoccurrence is common. To decrease the risk of recurrence, an emollient (petroleum jelly, A and D ointment) should be applied to the inner labia for 1 mo or longer at bedtime.</td>
</tr>
<tr>
<td>Lichen sclerosus (Fig. 549-4)</td>
<td>A sclerotic, atrophic, parchment-like plaque with an hourglass or keyhole appearance of vulvar, perianal, or perineal skin, subepithelial hemorrhages may be misinterpreted as sexual abuse or trauma. The patient can experience perineal itching, soreness, or dysuria</td>
<td>Diagnosis usually is made by visual inspection. Biopsy should be reserved for when the diagnosis is in question. Ultrapotent topical corticosteroids are the first-line therapy (clobetasol propionate ointment 0.05%) once or twice a day for 4-8 wk. Once symptoms are under control, the patient should be tapered off the drug unless therapy is required for a flare-up. In many girls, the condition resolves with puberty; however, this is not always the case and patients may require long-term follow-up.</td>
<td></td>
</tr>
<tr>
<td>Psoriasis</td>
<td>Children are more likely than adults to have vulvar psoriasis noted as pruritic, well-demarcated, nonscaly, brightly erythematous, symmetrical plaques. The classic extragenital lesion are similar but with a silver scaly appearance.</td>
<td>Diagnosis may be confirmed by locating other affected areas on the scalp or in nasolabial folds or behind the ears. Vulvar lesions may be treated with low to medium potency topical corticosteroids, increasing strength as necessary.</td>
<td></td>
</tr>
<tr>
<td>Atopic dermatitis</td>
<td>Chronic cases can result in crusty, weepy lesions that are accompanied by intense pruritus and erythema. Scratching often results in excoriation of the lesions and secondary bacterial or candidal infection.</td>
<td>It may be seen in the vulvar area but characteristically affects the face, neck, chest, and extremities. Children with this condition should avoid common irritants and use topical corticosteroids (such as 1% hydrocortisone) for flare-ups. If dry skin is present, lotion or bath oil can be used to seal in moisture after bathing.</td>
<td></td>
</tr>
<tr>
<td>Contact dermatitis</td>
<td>Erythematous, edematous, or weepy vulvar vesicles or pustules can result, but more often the skin appears infiltrated.</td>
<td>Associated with exposure to an irritant, such as perfumed soaps, bubble bath, talcum powder, lotions, elastic bands of undergarments, or disposable diaper components. Avoidance of irritant. Topical corticosteroids for flare-ups.</td>
<td></td>
</tr>
<tr>
<td>Seborrheic dermatitis</td>
<td>Erythematous and greasy, yellowish scaling on vulva and labial crural folds associated with greasy dandruff-type rash of scalp, behind ears and face.</td>
<td>Diagnosis usually is made by visual inspection. Gentle cleaning, topical clotrimazole with 1% hydrocortisone added.</td>
<td></td>
</tr>
<tr>
<td>Vitiligo (Fig. 549-5)</td>
<td>Sharply demarcated hypopigmented patches, often symmetric in vaginal and anal regions. May be present in periphery at body orifices and extensor surfaces.</td>
<td>Clinical. Test for associated illness if clinically warranted (thyroid disease, Addison disease, pernicious anemia, diabetes mellitus). If desired, treat limited lesions with low-potency corticosteroids or tacrolimus. See dermatologist for extensive lesions.</td>
<td></td>

MRSA, methicillin-resistant Staphylococcus aureus; TMP-SMX, trimethoprim-sulfamethoxazole.

frequent bathing, and application of water-repellant barriers such as zinc oxide. If diaper dermatitis persists after these conservative measures, or if the classic satellite lesions of Candida are present, treatment with an antifungal can decrease the inflammation.

**Physiologic Leukorrhea**

Neonates and peripubertal girls can present with a white or clear or mucus discharge, which is a physiologic effect of estrogen. Some girls complain of the moisture and mucus, but an explanation should reassure the patient and her mother.

**Genital Ulcers**

Acute genital ulceration of the vulva (Fig. 549-2) is described in young adolescents who are not sexually active and can occur in association with oral aphthous ulcers. Although linked to infectious causes such as Epstein-Barr, cytomegalovirus, mycoplasma, and influenza A, recent data suggest these ulcers may be idiopathic vulvar aphthoses.

Other potential etiologies include inflammatory bowel disease, Behçet disease, pemphigoid, Stevens-Johnson syndrome, drug eruption, or mouth and genital ulcers with inflamed cartilage (MAGIC syndrome).

These lesions usually appear on the mucosal surfaces of the introitus as painful red or white lesions that evolve into sharply demarcated red-rimmed ulcers with a necrotic or eschar-like base. The time course is generally 10-14 days until remission occurs. The lesions are quite painful and may require pain management and urinary diversion with a Foley catheter. Patients with acne-like genital ulcers may present with a fairly consistent picture of flu-like prodromal symptoms, dysuria, and
vulvar pain. One-third of patients present with a history of or develop oral ulcerations. Evaluation includes culture for herpes simplex virus to exclude this etiology. Special testing for systemic disease depends on history. Biopsies are usually nondiagnostic as they yield acute and chronic inflammatory changes. Figure 549-3 outlines suggested evaluation and management for initial and recurrent disease. Evaluation for Behçet disease (see Chapter 161) using the International Study Group diagnostic guidelines should be considered with recurrent or severe cases. (See Table 549-1 for other common etiologies.) Treatment of acute genital ulcers should include topical Xylocaine 2% jelly, sitz baths, good hygiene, and acetaminophen. Nonsteroidal antiinflammatory drug avoidance is suggested because of a possible causative link. Hospitalization may be required for pain management not controlled with oral narcotics, urinary retention requiring Foley catheterization, or for whirlpool debridement should hygiene become difficult. Antibiotic treatment is not required unless evidence of bacterial superinfection exists or the patient is immunocompromised. Insufficient evidence exists to recommend whether oral steroid treatment is effective but may be helpful in the setting of recurrent outbreaks. Ultrapotent topical steroids (clobetasol 0.05% ointment), however, are beneficial in oral aphthous ulcers and may prove helpful in acute genital ulcers as well.
secretions, as it is not necessary to place the swab into the vagina. The premoistened swab can be placed vertically between the labia minora to collect secretions, if necessary. Using a cystoscope with saline or water irrigation to gravity, endoscopic patient in an outpatient setting, or under general anesthesia if needed. If untreated, lichen sclerosus can lead to destruction and scarring of normal genital architecture, including labial resorption, obliteration of the clitoris, narrowing of the introitus, and painful fissures that may become secondarily infected. Once thought to resolve with puberty, this theory is now controversial and many postmenarchal adolescents still suffer from disease (Fig. 549-4). Lichen sclerosis may be treated with potent topical steroids, clobetasol propionate 0.05% applied once or twice daily until the symptoms resolve. Vitiligo is an acquired skin depigmentation resulting from an autoimmune process directed at epidermal melanocytes. Lesions appear as sharply demarcated patches of pigment loss, often symmetrically located around vagina and anal area. Similar lesions of hypopigmentation can be found surrounding body orifices and extensor surfaces (Fig. 549-5). Although diagnosis is clinical, there is an association with other autoimmune or endocrine disorders (hypothyroidism, Graves disease, Addison disease, pernicious anemia, insulin-dependent diabetes mellitus) and workup should include evaluation for at least thyroid dysfunction. Mild topical corticosteroid cream or ointment may be prescribed for children. Dermatologists may offer immunomodulators (tacrolimus), and phototherapy.

Vulvar psoriasis presents as pruritic, well-demarcated nonscaly, erythematous, symmetrical plaques that involve the vulva, perineum and/or gluteal folds. Lesions on the mons pubis may have the more characteristic scaly appearance. The classic signs of psoriasis may also be appreciated with pitting nail beds, posterior auricular erythema or a silvery scaling rash found elsewhere on the body. Many of the treatments used in adults may not be appropriate in children. Psoriasis may be treated with moisturizers, topical steroids, and light therapy. Teens may be treated with coal tar, retinoids, tacrolimus, and calcipotriene, which is a derivative of vitamin D3.

**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS**

Children with symptoms of vulvovaginitis often have had a previous evaluations and treatment failures. Cultures with sensitivities to test for specific pathogens may be obtained with cotton swabs or urethral (Calgiswab) swabs moistened with nonbacteriostatic saline. Use of a swab can cause discomfort or, rarely, minimal bleeding. The premoistened swab can be placed vertically between the labia minora to collect secretions, as it is not necessary to place the swab into the vagina.

**Dermatoses**

Dermatologic conditions often affect the vulvar area in children; it is important to determine if the girl presenting with vulvar irritation has a skin condition elsewhere on the body. Lichen sclerosus is commonly seen in the anogenital region and has a characteristic appearance of white skin changes associated with areas of erosion, ulceration, and petechia. This disease can cause severe discomfort and is most commonly presents with vulvar or perianal pruritus, dysuria, and constipation. Patients may also present without any symptoms, which may lead to underrecognition and under treatment. If untreated, lichen sclerosus can lead to destruction and scarring of normal genital architecture, including labial resorption, obliteration of the clitoris, narrowing of the introitus, and painful fissures that may become secondarily infected. Once thought to resolve with puberty, this theory is now controversial and many postmenarchal adolescents still suffer from disease (Fig. 549-4). Lichen sclerosis may be treated with potent topical steroids, clobetasol propionate 0.05% applied once or twice daily until the symptoms resolve.

Vulvar psoriasis presents as pruritic, well-demarcated nonscaly, erythematous, symmetrical plaques that involve the vulva, perineum and/or gluteal folds. Lesions on the mons pubis may have the more characteristic scaly appearance. The classic signs of psoriasis may also be appreciated with pitting nail beds, posterior auricular erythema or a silvery scaling rash found elsewhere on the body. Many of the treatments used in adults may not be appropriate in children. Psoriasis may be treated with moisturizers, topical steroids, and light therapy. Teens may be treated with coal tar, retinoids, tacrolimus, and calcipotriene, which is a derivative of vitamin D3.

**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS**

Children with symptoms of vulvovaginitis often have had a previous evaluations and treatment failures. Cultures with sensitivities to test for specific pathogens may be obtained with cotton swabs or urethral (Calgiswab) swabs moistened with nonbacteriostatic saline. Use of a swab can cause discomfort or, rarely, minimal bleeding. The premoistened swab can be placed vertically between the labia minora to collect secretions, as it is not necessary to place the swab into the vagina. Testing for gonorrhea and chlamydia may be done by culture or by nucleic acid amplification testing, depending on institutional or state and Centers for Disease Control guidelines. Tests for Shigella and H. influenzae might require special media and collection procedures.

If pinworms (see Chapter 294) are suspected, transparent adhesive tape or an anal swab should be applied to the anal region in the morning before defecation or bathing and then placed on a slide. Eggs seen on microscopic examination confirm the diagnosis, and sometimes the pinworms can be seen at the anal verge. Clinical history is often more indicative of disease than physical exam, and a negative tape test does not rule out this pathogen as a cause.

If the vaginal discharge is serosanguineous, if a foul odor is present, or if the discharge fails to respond to hygiene measures, consider presence of a vaginal foreign body (Fig. 549-6). If inspection suggests presence of a foreign body, the vagina can be irrigated, or an examination under anesthesia may reveal the foreign body. Vaginoscopy is an excellent diagnostic tool and can be performed in an unsedated cooperative patient in an outpatient setting, or under general anesthesia if necessary. Using a cystoscope with saline or water irrigation to gravity, insert the endoscopic device into the vagina, gently oppose the labia, the vagina will distend and the entire vaginal cavity and cervix may be easily assessed.

**TREATMENT AND PREVENTION**

The treatment of specific vulvovaginitis should be directed at the organism causing the symptoms (see Table 549-1). Treatment of non-specific vulvovaginitis includes sitz baths and avoidance of irritating or harsh soaps and chemicals and tight clothing that abrades the perineum. External application of bland emollient barriers such as nonprescription diaper rash medications and petroleum jelly may be helpful. Proper perineal hygiene is critical for long-term improvement. Younger children need supervised perineal hygiene, and caregivers should be advised to wipe the genital area from front to back. Use of a warm moistened washcloth or diaper wipe is helpful after initially wiping with toilet tissue. Girls should wear cotton underwear and limit time spent in tights, leotards, jeggings, tight jeans, and wet swimsuits. Soaking in warm clean bathwater for 15 min intervals (no shampoo or
bubble bath) is soothing and helps with cleaning the area. Parents should be counseled to avoid all scented, antiseptic, and deodorant-based soaps, and to eliminate the use of fabric softeners or dryer sheets when laundering undergarments.

*Bibliography is available at Expert Consult.*
Bibliography

Vaginal bleeding in infants and prepubescent children should always be evaluated. Bleeding can be seen as early as the 1st wk of life, resulting from endometrial sloughing associated with maternal estrogen withdrawal. A thorough history and physical must be obtained as the 1st step in evaluating the problem. Common causes for vaginal bleeding in children are vulvovaginitis, vaginal foreign bodies, dermatologic conditions, and urethral prolapse; less common causes are endogenous or exogenous estrogenic effects; and the most worrisome causes include neoplasms and trauma.

Vulvovaginitis (see Chapter 549) may be caused by respiratory, oral and fecal pathogens, some of which produce serosanguineous drainage (e.g., *Streptococcus, Shigella*) or cause vulvar bleeding resulting from irritation and excoriation of the skin. Prepubertal girls are at a higher risk for developing these irritations because the protective labia of pubertal girls are not fully developed and thus, the vaginal opening and vagina are easily more exposed to irritants. Further, the hypoestrogenic vaginal mucosa is thin and lacks the protective effects of an acidic pH from lactobacilli. The alkaline vaginal pH noted in prepubertal girls results in an environment more prone to infection. Hand-washing, improved perineal hygiene (wiping front to back, use of wet wipes after bowel movement), and avoidance of topical irritants, chemicals, and perfumed or deodorant soaps and bubble baths will reduce nonspecific vulvovaginitis. External application of bland emollient barriers such as over the counter diaper rash ointments or petroleum jelly may helpful (see Table 549-2 in Chapter 549). Antibiotics will help with recurrent or persistent infections if a specific pathogen is identified by culture.

Hematuria is suspected when the urine is red or brown. Gross hematuria may be confused with vaginal bleeding. A positive urinary dipstick can confirm blood, but pigments and metabolites may also cause red or brown urine (see Chapter 509). The cause of gross hematuria in symptomatic children is usually elicited by a complete history, physical examination and urinalysis. Additional diagnostic studies may include ultrasound of the kidneys and bladder, urine culture, measurements of urine calcium/creatinine, and serum C3 and creatinine. Treatment depends on the diagnosis.

Dermatoses may present with bleeding. Lichen sclerosus (see Fig. 549-4 and Table 549-1 in Chapter 549), is characterized by chronic inflammation, intense pruritus, loss of normal architecture, thinning and whitening of the vulvar and perianal skin often in a butterfly or keyhole distribution. Petechiae or blood blisters can arise and be mistaken as a sign of sexual abuse. Diagnosis is based on these classic clinical characteristics, but may be confirmed by a tissue biopsy if necessary. As a first-line treatment, potent topical steroids, such as clobetasol propionate ointment 0.05%, may be applied sparingly to the affected tissue 1-2 times a day under physician supervision; they usually result in improvements in appearance and pruritus. The steroid should be used for the shortest duration necessary then be stopped or tapered. Flare-ups can occur and require retreatment.

Foreign bodies are a common cause of vaginal bleeding, and children present with blood-stained and foul-smelling discharge. The most common object found in prepubertal girls is toilet paper. A physical exam in knee–chest or frogleg position can sometimes reveal the object. Vaginal irrigation may be done in the office setting using a small feeding tube, a syringe, and warm water. If the object is not visible on examination, irrigation is unlikely to remove it and examination under anesthesia and vaginoscopy are often required. Vaginoscopy not only allows removal of a foreign object but also can facilitate diagnosis of other causes of the bleeding.

Trauma to the vulva or vagina is especially concerning. Most of these injuries are accidental, but physical and sexual abuse must be ruled out (see Chapter 40). Straddle injuries such as falling on the cross bar of a bicycle or slipping in the bathtub may result in bruising, hematomas, and lacerations. In general, if the trauma is accidental, the hymen and vagina are spared as most accidental injuries involve the mons and labia. *If there are no eyewitnesses to the injury, if there is no history to explain the clinical findings, and especially if there is a laceration of the hymen, abuse must be considered in the differential diagnosis, and a forensic interview of the patient and family should take place.* If the injury is penetrating, further examination and imaging are necessary to evaluate the urethra, bladder, anus, and intraabdominal structures. General anesthesia may be needed to fully assess injuries and allow adequate repair; while minor lacerations may be repaired in a cooperative child under sedation or local anesthesia. If the patient is able to
void spontaneously, nonexpanding hematomas can be observed and treated with ice, pressure, and pain medications. Large expanding hematomas should be carefully evaluated and may require drainage, ligation of the bleeding vessels, and/or placement of a closed suction drain, especially if the overlying skin is showing signs of necrosis. A Foley catheter should be placed for children who are having difficulty with voiding.

Urethral prolapse (see Chapter 544) is another potential cause of bleeding in the prepubertal girl. The patient may present with a circular protrusion of the urethral mucosa through the external meatus forming a friable vulvar mass. Downward traction at the introitus enables visualization of the vaginal orifice separate from the urethral mass and assists with confirming the correct diagnosis. Patients may be asymptomatic or present with bleeding, dysuria, or difficulty with urination. Low estrogen state, trauma, chronic cough, and constipation are believed to be predisposing factors. Treatment is conservative, with application of estrogen cream at the area of prolapse twice daily for 1-2 wk and then, if prolapse is still present, continued use until the prolapse resolves. Surgical excision is very rarely necessary to remove necrotic tissue.

Neoplasms of the vulva and vagina are rare (see Chapter 553). Infantile hemangiomas are the most common benign vascular neoplasm of infancy, affecting 5% of all infants. Most lesions proliferate then involute, and only a few require intervention. Hemangiomas of the perineum may be associated with spinal dysraphism, so a neurologic assessment should be performed. Intralesional and systemic steroids have been used to treat infantile hemangiomas. Propranolol therapy results in a good response rate. Laser therapy and surgical excision are sometimes used.

Like hemangiomas, hymenal polyps are usually benign. If these polyps are noted at birth, they generally regress after maternal levels of estrogen decrease in the infant. If hymenal polyps persist, grow, or cause discomfort they may be removed. Vaginal polyps, especially if they cause bleeding, should be removed (not followed) and sent for pathologic evaluation. Yolk sac (endodermal sinus) tumors of the vagina are rare but may cause vaginal bleeding. Serum α-fetoprotein is a reliable marker. Rhabdomyosarcoma is the most common soft-tissue sarcoma of childhood. In children, the most common sites are the head and neck (35%) and genitourinary region (25%) (see Chapter 500). Rhabdomyosarcoma arising in the genitourinary tract are commonly the sarcoma botryoides variant and are typically seen in the 1st decade, often before age 3 yr, and present with vaginal discharge and bleeding. Treatment consists of a multimodal approach, including surgery, radiation therapy, and chemotherapy. The survival rate is >90% when an early diagnosis is made.

Vaginal bleeding can be a presenting sign of precocious puberty, which is defined as pubertal development that is 2.5-3.0 SD earlier than the average age. Guidelines for the evaluation of premature development state that pubic hair or breast development requires evaluation generally when it occurs before age 7 yr in non–African-American girls and before age 6 yr in African-American girls (see Chapters 561 and 562). Rapidity of pubertal progression, such as Tanner stage 3 breast development before 8 yr of age, may also require evaluation. The most common etiology is gonadotropin-dependent or central precocious puberty (see Chapter 562.1) where there is premature enhancement of pulsatile gonadotropin-releasing hormone release resulting in ovarian follicle growth and estrogen production. Gonadotropin-independent precocious puberty, where estrogen production is not under hypothalamic control and is produced peripherally, such as from an ovarian/adrenal tumor or McCune Albright syndrome, is less common.

A thorough physical exam must be done, looking for secondary sex characteristics and documenting breast and pubic hair development using the Sexual Maturation Index (Tanner Staging; see Chapter 110.1). Documenting height and weight on a growth chart will assist in identifying accelerated growth velocity. Diagnostic tests include a left wrist x-ray to look for advanced bone age. Elevated serum luteinizing hormone levels are highly suggestive of central precocity, but the gold standard is measurement of gonadotropins after gonadotropin-releasing hormone or gonadotropin-releasing hormone-agonist stimulation. In all cases of central precocious puberty, MRI imaging of the brain is needed to determine if a tumor is present. Pelvic ultrasound might show presence of ovarian or adrenal pathology or uterine maturation in response to estrogen. Benign premature ovarian follicles or malignant ovarian germ cell tumors can produce elevated serum estradiol levels >100 pg/mL. If the estradiol is elevated, pelvic imaging by transabdominal ultrasound is mandated. Usually benign ovarian follicles produce short periods of estrogen elevation which is enough to stimulate the endometrial lining and result in endometrial shedding. Usually by the time the pelvic ultrasound is obtained the follicular structure has collapsed and resolved and the estrogen level has dropped to prepubertal range. If indicated central precocious puberty can be suppressed with leuprolide injections or histrelin implants. Germ cell tumors are treated by excision, staging and chemo or radiation therapy by protocols provided by oncologists.

Juvenile hypothyroidism commonly causes pubertal delay. Patients with severe, long-standing and untreated hypothyroidism may present with premature breast development, vaginal bleeding and abdominal distention resulting from ovarian enlargement and possibly ascites associated with deceleration of linear growth. A proposed mechanism is thyroid-releasing hormone-associated elevations of thyroid-stimulating hormone crossreacting with follicle-stimulating hormone resulting in follicle maturation and estradiol production. Treatment of the hypothyroidism results in improvement and reversal of symptoms.

Another etiology for childhood vaginal bleeding is exogenous exposures to estrogens. These exposures can occur from ingestion of birth control pills, foods, beauty products, and plastics that contain estrogen or estrogen-like components. Several other studies have assessed the risk of bisphenol A leaching from plastic cups and bottles. The importance of this is still being studied, but bisphenol A is known to have an estrogenic effect and thus could potentially be a cause for vaginal bleeding if ingested in high levels.

Vaginal bleeding in the prepubertal girl or infant can have many causes, which range from benign to malignant. A thoughtful history and physical examination must be done to identify the source of bleeding so that treatment can occur. The risk benefit of any therapy should be reviewed carefully with the family.

Bibliography is available at Expert Consult.
Bibliography
Presenting concerns of girls with breast disorders typically including the development or appearance of their breasts, breast pain, nipple discharge, or concerns about the presence of a mass. Although children and adolescents are very unlikely to have malignant or life-threatening breast problems, this population of patients should be referred to practitioners who have experience and familiarity with the immature and developing breast to avoid overtreatment with unnecessary diagnostic or surgical procedures.

**BREAST DEVELOPMENT**

Development of the breast begins around wk 5 of gestation, when the ectoderm on the anterior body wall thickens into 2 ridges known as the mammary ridges. They extend from the area of the developing axilla to the area of the developing inguinal canal. The ridge above and below the area of the pectoralis muscle recedes in utero, leaving the mammary primordium, which is the origin of the lactiferous ducts.
The initial lactiferous ducts form between wk 10 and 20 and become interspersed through the developing mesenchyme, which becomes the fibrous and fatty portions of the breast. The breast bud, under the stimulation of maternal estrogen, becomes palpable at wk 34 of gestation. This breast bud regresses within the 1st mo of life, because the estrogen stimulation is no longer present. The areola appears at 5 mo of gestation, and the nipple is seen shortly after birth. It is initially depressed and later becomes elevated.

Thelarche, or the onset of pubertal breast development, is hormonally mediated and normally occurs between the ages of 8 and 13 yr, with an average age of 10.3 yr. The initiation of thelarche and progression in females is affected by race, with normal thelarche occurring earlier in African-American girls than in white or Asian girls. This occurs when the hypothalamus releases gonadotropin-releasing hormone, which stimulates the pituitary gland to produce follicle-stimulating hormone and luteinizing hormone, which then stimulates the ovaries to produce estrogen. The estrogen leads to breast development.

Once thelarche is initiated, normal development of the breast occurs over 2-4 yr and is classified by the sexual maturity rating system (also known as Tanner Staging) into 5 stages (Chapter 110.1). Maturation can sometimes occur asymmetrically owing to fluctuation of the hormonal environments and various end organ sensitivities. Lack of development by age 13 yr is considered delayed and warrants endocrinology evaluation. Menarche usually occurs approximately 2 yr after initiation of breast development.

**Breast Examination**

A breast examination should be included in the annual examination of all children and adolescents. Examination of the newborn includes assessment of breast size, nipple position, presence of accessory nipples, and nipple discharge. Examination of the prepubertal girl includes inspection and palpation of the chest wall for masses, pain, nipple discharge, and signs of premature thelarche. Examination of the adolescent is performed with the patient in the supine position; the arm ipsilateral to the breast that is being examined should be placed next to the patient’s head. The breast tissue is examined with the flat pads of the middle fingers and the examiner can feel for abnormalities on the breast with a pattern similar to spokes on a wheel, in a circular clockwise pattern with concentric circles or by moving in a rotary fashion around the breast. Whatever the method used, the goal is to palpate all the breast tissue in a uniform fashion. The sexual maturity rating should be noted and axillary, supraclavicular, and infraclavicular nodes evaluated for lymphadenopathy. The areola should be compressed to assess for nipple discharge.

**Breast Self-Examination**

Controversy exists as to the utility of breast self-examination in the adolescent population. Experts believe that it might be ill advised to encourage breast self-examination in the adolescent because of a potential for unnecessary anxiety and possible unwarranted treatment in a population that is at low risk for malignant disease. The American College of Obstetricians and Gynecologists states that despite a lack of definitive data for or against breast self-examination, breast self-examination may be recommended beginning at age 19 yr. Women with previous exposure to therapeutic chest radiation therapy are advised to begin breast self-examination 8 yr after radiation therapy.

**Abnormal Development**

**Neonatal Breast Abnormalities**

The condition in which breasts enlarge in the newborn period is neonatal breast hypertrophy. This is quite common in term infants of either sex and can occur as a result of elevated circulating maternal endogenous steroid hormones in late gestation. As maternal estrogen levels fall, prolactin levels can increase and the breasts can produce a clear or cloudy (milk-like) nipple discharge (“witch’s milk”) in male and female infants. Repeated manipulation of the breast can exacerbate the condition. On occasion, the hypertrophy is associated with mastitis caused by a staphylococcal or streptococcal infection; antibiotics should be administered.

**Precocious Puberty**

Premature thelarche is usually an isolated condition and is more common than previously thought. In one study, patients with a sexual maturity rating 2 or greater at 7 yr of age were 10.4% of white, 23.4% of black non-Hispanic, and 14.9% of Hispanic girls. However, it may also be the first symptom of precocious puberty. Precocious puberty occurs in 14-18% of girls with premature thelarche (see Chapter 562). Serial examinations, with particular emphasis on growth velocity, secondary sex characters such as pubic hair, pigmentation of the labia or areola, or vaginal bleeding are imperative to identify precocious puberty. Unless there are associated signs of precocious puberty, the parents should be reassured and the child should be followed.

**Amastia**

Complete absence of the breast, or amastia, is rare and is thought to occur from lack of formation or obliteration of the mammary ridge. Amastia is usually unilateral and can be congenital or associated with systemic disorders (e.g., ectodermal dysplasia, Crohn disease) or endocrine disorders (e.g., congenital adrenal hyperplasia, gonadal dysgenesis, hypogonadotrophic hypogonadism). Novel gene mutations have been discovered that may be linked to syndromic amastia, including PTPRF, a protein tyrosine receptor type F gene, and ectodysplasin A receptor (EDAR). It can be associated with anomalies of the underlying mesoderm, such as abnormal pectoralis muscles seen in Poland syndrome (aplasia of the pectoralis muscles, rib deformities, webbed fingers, and radial nerve aplasia) (Fig. 551-1). Amastia or hypomastia can also be iatrogenic, resulting from injuries sustained during thoracotomy, chest tube placement, radiotherapy, severe burns, and inappropriate biopsy of the breast bud. Treatment is surgical correction.

**Polymastia and Polythelia**

Supernumerary breast tissue (polymastia) and accessory nipples (polythelia) occur in approximately 1-6% of the population (Fig. 551-2). The abnormally placed tissue can be seen anywhere along the mammary ridges as a result of incomplete involution but is usually noted on the chest, upper abdomen, or just inferior to the normally positioned breast. There is an association between polythelia and anomalies of the urinary and cardiovascular system. Surgical excision of the accessory breasts or nipple is not usually needed. Resection of accessory tissue may be warranted if the patient has pain or for cosmetic reasons.

**Breast Asymmetry and Hypomastia**

Some degree of asymmetry is normal in women, and it may be more pronounced during puberty while the breasts are developing.
Hypoplasia of the breasts varies in degree from a nearly total absence of breast tissue to well-formed breasts that are considered by the patient to be too small. There are several causes for poor or absent breast development. The onset of breast development may be delayed with normal secondary sex characters; the breasts develop slowly but are normal in all other respects; a patient's family history might include late breast development. Other causes include ovarian dysfunction, hypothyroidism, and chest wall irradiation or surgery. Hypoplastic breast tissue can also be associated with a tuberous breast anomaly. Treatment depends on the underlying cause. Patients with mild asymmetry and with no other associated pathology should be reassured. Surgical correction is an option for women with marked asymmetry and with no other associated pathology should be reassured.

### Juvenile or Virginal Hypertrophy

Spontaneous massive growth of the breasts during puberty and adolescence is thought to be the result of excessive end-organ sensitivity to gonadal hormones, although both the hormone receptors and serum estradiol levels are normal. The underlying cause, if any, should be determined and removed (Table 551-1). When growth is extreme it is termed macromastia or gigantomastia. It is more commonly bilateral, often occurs over a brief period, and most commonly affects adolescent girls (Fig. 551-3). Physical and psychologic problems can affect posture and quality of life. Strong emotional support should be provided as this can affect an adolescent's self-esteem at a vulnerable time in her psychologic development. Management should be individualized and may range from reassurance or the use of supportive brassieres to reduction mammoplasty or even mastectomy. Medical therapy, such as tamoxifen, is available to slow breast growth in extreme cases until surgery can be performed. Surgical intervention often necessitates relocation of the nipple, which can result in decreased sensation and altered lactation, and it is not uncommon for the lesion to recur.

### INFECTIONS

Mastitis is the most common infection of the breast. Although it is most common in lactating mothers, it can occur in young infants and adolescents. Neonatal mastitis is an infection that usually occurs in term or near-term infants. It should be treated aggressively to reduce the risk of forming abscesses. Adolescents can develop nonlactational mastitis or a breast abscess for unknown reasons, as a result of irritation of the skin (through shaving or nipple stimulation), trauma, a foreign body (e.g., piercing), ductal abnormality (such as ductal ectasia), or infection of an epidermal cyst. The initial therapy of all breast infections is antibiotics and analgesics. Staphylococcus aureus (see Chapter 181.1) or anaerobic bacilli (bacteroides) are the offending organism is almost all cases, and methicillin-resistant S. aureus coverage should be considered in communities where prevalence is high. Owing to the potential for breast abscess, the neonatal population should be treated with parenteral antibiotics for methicillin-resistant S. aureus or guided by gram stain, when available. Adolescents may be initially treated with warm compresses and oral antibiotics. Abscesses should be surgically evaluated (with ultrasound guidance if necessary) and drained as necessary. If incision and drainage is performed, a small, periareolar incision is indicated.

### TRAUMA AND INFLAMMATION

Breast trauma is common in adolescent girls participating in contact sports. The trauma usually takes the form of contusion or hematoma and can resolve spontaneously or may be associated with late cystic changes in the breast or fibrosis with retraction of the skin or the nipple over the injured area.

### NIPPLE DISCHARGE

Nipple discharge must be carefully evaluated and a distinction made among galactorrhea (milky white discharge), blood, or other discharge (Table 551-2). A careful history and physical examination directed at the possible etiologies of galactorrhea will help the practitioner determine the etiology. Examination of the discharge assists in diagnosis. Benign conditions are usually associated with a milky, sticky, thick discharge; infection is associated with a purulent discharge; intraductal papilloma and cancer are associated with a serous, serosanguineous, or bloody discharge. Preoperative evaluations by mammography, hemoccult, ductography, and cytology are poor predictors of histologic diagnosis. Therefore, patients with pathologic nipple discharge should undergo biopsy for accurate diagnosis.

### Galactorrhea

Cytologic evaluation of nipple discharge is not recommended. Serum pregnancy testing and prolactin and thyroid levels are obtained to rule out the presence of a thyroid abnormality, a pituitary prolactinoma, and pregnancy (in the postpubertal adolescent). If the prolactin level...
is elevated, visual field studies and a head MRI might reveal presence of a pituitary adenoma (see Chapter 560). Treatment is directed by results of history, physical exam, and lab studies. Patients should be instructed to avoid nipple stimulation and stop any offending drugs. Hypothyroidism should be treated and prolactin tumors managed with appropriate medical or surgical care. Treatment of galactorrhea (not thyroid related) consists primarily of dopamine agonists such as bromocriptine or cabergoline. Surgical intervention, usually transphenoidal hypophysectomy, is rarely required.

**Bloody Discharge**

In adolescent athletes, bloody discharge may be due to chronic nipple irritation (jogger’s nipple), discharge from the ducts of Montgomery (on the edge of the areola, not through the nipple) or duct ectasia. Cytologic assessment should be performed. Surgical consultation for a mass is indicated because intraductal breast papillomas have occurred in adolescents. However, there have been no reported cases of breast cancer in infants. Bloody nipple discharge in infants is most likely from mammary duct ectasia, and if the following studies are normal (pro-lactin, estradiol, thyrotrpin, and ultrasound) then watchful waiting is considered because the risk of primary cancer is very low in this population. Bloody nipple discharge in infants should always be evaluated as a side effect of cimetidine and is reversible when the medication is stopped.

**MASTALGIA**

The most common causes of breast pain in adolescents are exercise and benign breast changes. Physiologic swelling and tenderness occur on a cyclic basis, most commonly during the premenstrual phase, and are secondary to hormonal stimulation and resulting proliferative changes. Hormonal imbalance can cause exaggerated responses in the breast tissue, especially in the upper and outer quadrants. Nodularity, poorly localized tenderness, and a soreness radiating to the axilla and arm are usual accompanying findings. The preferable term for these changes is benign breast changes rather than fibrocystic disease. Treatments recommended for this condition and exercise-induced pain include a firm supportive sports-type bra, heat, and analgesics. Oral contraceptives often improve the breast pain. A course of nonsteroidal antiinflammatory drugs is also effective. Methylenanthines (caffeine in coffee, tea, carbonated drinks) and smoking should be eliminated. Evening primrose oil and vitamin E are popular but unproven treatments.

**BREAST MASSES**

**Peripubertal Masses**

A mass in the developing breast can be of concern to the adolescent and her family. Initial breast development at the onset of thelarche can be asymmetric and thus mistaken for a “mass.” The breast bud is palpable in these cases and should be distinguishable. Such asynchronous thelarche should be recognized to avoid biopsy and potential injury to the maturing breast. If there is any question, ultrasound can be used to evaluate for a mass. Unilateral thelarche has also been reported as a side effect of cimetidine and is reversible when the medication is stopped.

**Common Adolescent Breast Masses**

Table 551-3 shows the differential diagnosis for breast masses in the adolescent patient. The patient should be questioned about the variation in symptoms with the menstrual cycle, associated symptoms such as nipple discharge, recent trauma to the breast, family history of breast masses or cancer, and history of chest radiation or malignancy. Because breast cancer in the adolescent is extremely rare, masses can be expectedly managed for extended periods with little concern for malignancy in this population.

The most common solid mass seen in adolescent girls is the fibroadenoma. Fibroadenomas are most often located in the upper outer quadrant of the breast. The average size is 2-3 cm, and 10-25% of patients have multiple lesions. The physical examination is usually diagnostic because these lesions are well circumscribed, rubbery, mobile, and not tender. In equivocal cases, an ultrasound may be helpful in making the diagnosis. Mammography is not indicated in the adolescent patient.

Fibroadenomas can develop because of a local exaggerated response to estrogen stimulation, and they can enlarge during the menstrual cycle. These lesions may be safely watched for at least 2 menstrual cycles, and some investigators suggest observation until adulthood. Approximately 10% of fibroadenomas regress spontaneously. The option of expectantly managing the patient until adulthood should be considered because the risk of primary cancer is very low in this population. If expectant management is chosen, serial ultrasounds every 6-12 mo may be done to ensure that the mass does not have malignant characteristics on imaging and that it is not enlarging or changing in contour until it starts regressing at which time the ultrasounds can be done on longer intervals. Approximately 4% of fibroadenomas grow, and so fine-needle aspiration or excision is recommended when a mass is enlarging, grows >5 cm (because of the risk of giant fibroadenoma or cystosarcoma phyllodes), or the mass is causing anxiety to the patient.
patient or her family. Combined estrogen-progesterone birth control pills have been found to be protective of fibroadenomas.

Cysts are very common masses seen in the pediatric breast. Cysts vary in size over the course of a menstrual cycle, so a patient with a possible cyst should be reexamined a few weeks after the initial evaluation to see if the mass is still present. If a mass persists, then it may be imaged by sonography or aspirated with a needle to evaluate if it truly is a cyst. Aspirated fluid that is clear may be discarded. Bloody fluid and other aspirated material should be sent for cytology. Cystic lesions that resolve with aspiration should be reevaluated in 3 mo. If they recur they should be evaluated with sonography.

Malignant Masses
Primary breast cancer is extremely rare in adolescents. Surveillance Epidemiology and End Results data from 1975-2009 establishes an incidence of invasive breast cancer of 0.2/100,000 for females ages 15-19 yr and 1.6/100,000 for females ages 20-24 yr. Although malignancy is rare, lesions with suspicious imaging findings or progressive growth should undergo cytologic or histologic examination. A small study in Austria noted a 4.7% malignancy rate among palpable masses in teens.

Cystosarcoma phylloides can occur in adolescents and has been reported in a child as young as 10 yr old. It is characterized by asymmetric breast enlargement in association with a firm, mobile, circumscribed mass. It can mimic a giant fibroadenoma. The tumor often grows rapidly and can become quite large. The majority of these tumors have a favorable prognosis, but malignant cystosarcoma phylloides has been reported to recur both locally and with metastases. Fatal metastatic cystosarcoma phylloides in an adolescent has occurred. Excision with 1 cm margins is the preferred initial therapy in adolescent patients, regardless of the histologic classification of the lesion.

Juvenile papillomatosis is a marker for increased breast cancer risk in family members, and in patients with these, up to 15% may have a juvenile secretory carcinoma. Treatment of juvenile papillomatosis is total resection of the lesion with preservation of the breast.

Secondary cancers in adolescents with previous therapeutic radiation to the chest or with malignancies with the potential to metastasize to the breast should be monitored more closely for breast masses. Rhabdomyosarcoma is the most common to metastasize to the breast. Breast tumors also may be the first manifestation of relapse (extramedullary) in acute lymphoblastic leukemia.

Imaging of Breast Masses
Because the dense breast tissue of the adolescent obstructs the visualization of a palpable mass, mammography is not advised for this age group. Ultrasonography is the imaging modality of choice for breast abnormalities in the pediatric population. Color Doppler ultrasound can be useful in evaluating breast abnormalities such as fibroadenomas or abscesses.

Recommendations for Daughters of Women with Breast Cancer
Risk Reduction
There are a limited number of things that young women can do to lower their risk of breast cancer. The American Cancer Society recommends regular physical activity, limiting alcohol, and maintaining a healthy weight. Breastfeeding has a slight effect on breast cancer risk and that effect is only among women who have breastfed for a long time. Breastfeeding seems to be more protective against the most aggressive types of breast cancer, including tumors in women with mutations in the BRCA-1 gene, hormone-receptor negative, and possibly triple-negative tumors.

Screening Procedures
Breast self-examination is an option for women starting in their 20s. Women should be told about the benefits and limitations of breast self-examination. Women should report any breast changes to their health professional. Women in their 20s and 30s should have a clinical breast exam as part of a periodic (regular) health exam by a health professional, at least every 3 yr. After age 40 yr, women should have a breast exam by a health professional every year and a screening mammogram every year and should continue to do so for as long as they are in good health.

Genetic Testing in Children
Genetic testing for mutations in cancer susceptibility genes in children is particularly complex. Both parents and providers may request or recommend testing for minor children; however, many experts (including the American Society of Clinical Oncology) recommend that unless there is evidence that the test result will influence the medical management of the child or adolescent, genetic testing should be deferred until legal adulthood (18 yr or older) because of concerns about autonomy, potential discrimination, and possible psychosocial effects.

COSMETIC SURGERY
A dramatic increase in adolescents desiring breast augmentation has occurred since the turn of the century. Breast augmentation in adolescents is discouraged owing to associated psychologic and physical immaturity. The American Society of Plastic Surgeons discourages breast augmentation in girls younger than age 18 yr for purely cosmetic reasons. The FDA also considers breast implants in adolescents younger than age 18 yr for solely cosmetic reasons to be an off-label use.

Breast reduction surgery might be considered when an adolescent is bothered by extremely large breasts that result in neck and back pain and prevent participation in sports. Breast reduction allows these girls to feel less self-conscious, have less pain, and be more active. Also girls with marked asymmetry in breasts from the pathologies noted earlier can feel self-conscious and request breast surgery. Before performing breast-altering surgery, practitioners must ensure proper selection of teens and families who have an appropriate understanding of the risks and benefits of surgery and realistic expectations of the procedure.

Polycystic Ovary Syndrome and Hirsutism

Mark Gibson and Heather G. Huddleston

POLYCYSTIC OVARY SYNDROME

Etiology and Definition

Polycystic ovary syndrome (PCOS) is a common disorder of reproductive hormone function that is characterized by the triad of oligoovulation or anovulation, clinical or biochemical hyperandrogenism, and ovaries with a polycystic morphology on ultrasound examination ($\geq 12$ follicles in 1 ovary and/or ovarian volume $>10\ mm^3$). Various expert bodies prioritize these elements differently for establishing the diagnosis, and few require the presence of all 3 (Table 552-1). Hyperandrogenism with ovulatory dysfunction (with exclusion of other causes) is most often considered sufficient for diagnosis in the United States. Abnormalities commonly associated with PCOS include obesity, insulin resistance, and the metabolic syndrome, but the phenotype is variable and affected individuals may display none of these. The disorder, affecting 5-8% of women of reproductive age, typically emerges in adolescence when a normal menstrual pattern is not established and there is clinical evidence of androgen excess.
**Pathology Pathogenesis and Genetics**

PCOS has a high concordance rate in twins, and in some studies either epigenetic or dominant inheritance patterns are observed. Nonetheless, a consistent hereditary pattern has not been identified.

Gonadotropin dysregulation with increased luteinizing hormone (LH) pulsatility and abnormally high ratios of circulating LH to follicle-stimulating hormone (FSH) are found in many patients with PCOS. Increased ovarian production of androgen in response to LH and impaired folliculogenesis owing to lower FSH are attributed to this gonadotropic pattern. Abnormal regulation of gonadotropin-releasing hormone agonist and abnormal gonadotropin secretion more likely reflect the abnormal hormonal milieu of the syndrome than explain its origin (Fig. 552-1). An increased ratio of circulating levels of LH:FSH is not a diagnostic criterion for PCOS.

Alterations in activities of steroidogenic enzymes that would explain ovarian androgenic hyperfunction are seen in PCOS subjects, but they are not consistently present in all patients and it is unclear whether these alterations are a cause of PCOS or a consequence of ovarian dysregulation. The mass of ovarian stromal cells responsible for androgen production is increased, and surgery that reduces this ovarian component (ovarian wedge resection, or laparoscopic ablative procedures) reduces circulating androgen levels and often restores ovarian cyclicity. Patients with hyperandrogenic congenital or adult-onset adrenal hyperplasia exhibit PCOS-like ovarian dysfunction that can be reversed by reducing the adrenal-derived androgens with glucocorticoid therapy. A primary role for androgen excess in the pathophysiology of all instances of PCOS seems unlikely; many patients have minimal hyperandrogenism, and elimination of androgen excess (with gonadotropin-releasing hormone agonists) does not affect associated insulin resistance.

Measures of insulin resistance are greater and more prevalent among women with PCOS than controls even when accounting for body mass index (BMI). Insulin enhances ovarian androgen production directly and contributes to elevations of free testosterone levels through its suppression of hepatic production of sex steroid–binding globulin. Treatment with insulin sensitivity–enhancing agents that can reduce insulin levels is associated with modest reductions in measures of androgen excess and, in some patients, restoration of regular ovulation. The association of insulin resistance with weight might explain the appearance of features of PCOS among some women who gain weight as well as the resolution of PCOS among affected women who lose weight.

**Clinical Manifestations**

PCOS, a lifelong disorder, commonly becomes manifest as puberty progresses, but its onset can occur later during young adulthood.

**Figure 552-1** Schematic of pathophysiology of polycystic ovary syndrome and mechanism of therapeutic drugs. DHT, dihydrotestosterone; LH, luteinizing hormone; OCPs, oral contraceptive pills; SHBG, sex hormone-binding globulin. (Adapted from Hassan A, Gordon CM: Polycystic ovary syndrome in adolescence, Curr Opin Pediatr 19[4]:389–397, 2007.)
Clinical hallmarks are menstrual abnormalities and manifestations of hyperandrogenism but the severity of the disorder is variable (Table 552-2). Ovulation is typically irregular or absent, and menses are consequently irregular or absent. When menstrual bleeding does occur, it may be anovulatory bleeding, which is often heavy and/or protracted as a result of an extended period of unopposed endometrial growth. Alternatively, bleeding can be relatively normal in character as a consequence of a preceding ovulation. Protracted spells of anovulation, with accompanying unopposed estrogen is a risk factor for endometrial hyperplasia, and more severe premalignant and frankly malignant changes may eventuate.

The diagnosis of PCOS in adolescents may be made on the basis of a lack of resolution of the normal pattern of anovulatory menstrual cycles present in the 1st 2 postmenarchal years. Less commonly, the diagnosis is made in the setting of primary amenorrhea. Serum androgen levels may be elevated and clinical findings of androgen excess are common, although distinction of normal androgenic expressions of puberty (acne, mild hirsutism) from early manifestations of PCOS may be difficult and serum hormonal testing may be helpful.

Obesity is common among affected women, and in some patients expression of PCOS features is conditional on elevation of BMI and reversible with weight loss. However, there is a subset of patients present with a “lean” PCOS phenotype and thus absence of excess weight should not preclude consideration of the PCOS diagnosis. PCOS is associated with an increased prevalence of insulin resistance and type 2 diabetes independent of the tendency for many affected patients to have an elevated BMI. Additionally, PCOS confers a substantial and specific increase in risk for metabolic syndrome (hyperlipidemia, insulin resistance, type 2 diabetes) in adolescent girls after accounting for BMI.

**Laboratory Findings, Diagnosis, and Differential Diagnosis**

The diagnosis of PCOS requires exclusion of disorders that would otherwise account for hyperandrogenism and anovulation. Serum 17-hydroxyprogesterone should be measured when there is clear androgen excess to screen for adult-onset 21-hydroxylation deficiency (see Chapter 576). In the adolescent with amenorrhea but minimal hyperandrogenic findings, consideration should be given to functional hyperprolactinemia, FSH, and thyroid-stimulating hormone, respectively.

The diagnosis of PCOS is confirmed from the constellation of oligomenorrhea or anovulation, androgen excess (clinically or with biochemical confirmation), and typical ovarian morphology on ultrasound. Various experts weigh these 3 features differently and do not, as a rule, require the presence of all (see Table 552-1). Young women often exhibit the ovarian appearance of PCOS without any other evidence, and not all patients with PCOS by the criteria of hyperandrogenism and ovulatory dysfunction exhibit ovarian changes typical of PCOS. Ultrasound study to diagnose PCOS is not always required if oligovulation and features of androgen excess are present. Clinical androgen excess (particularly acne) often appears in late puberty and does not necessarily signal PCOS. Nevertheless, young women with persistent oligovulation or anovulation, accompanied by androgen excess, will likely have persistence of these symptoms and should be considered to have PCOS.

Insulin resistance is common among women with PCOS, and although not requisite for diagnosis, should be considered when PCOS is likely. Adolescents with hyperandrogenemia and anovulation should be evaluated for diabetes or impaired glucose tolerance with a 2 hr (75 g glucose load) glucose tolerance test.

**Complications and Long-Term Outlook**

Fertility management, prevention of endometrial cancer, and reduction in the likelihood and severity of the common accompanying metabolic disorders are long-term tasks for the PCOS patient and her healthcare providers (Table 552-3). Notwithstanding its reversibility with weight loss in some patients and a tendency to ameliorate in some women later in reproductive life, PCOS usually requires management throughout the reproductive years. Young patients should be counseled that modern fertility management allows most affected women to have children without great difficulty, and they should also know that the disorder does not confer reliable protection from unintended pregnancy. Endometrial cancer can develop as early as the 3rd decade in women with PCOS who are not managed with progestins or ovulation induction; patients should understand the importance of long-term strategies for endometrial protection. Impaired glucose tolerance, type 2 diabetes, and metabolic syndrome are more common among obese adolescents with PCOS; their prevalence increases over time. Weight control through diet and lifestyle measures, detection and management of impaired glucose tolerance and diabetes, and management of abnormal lipids are targets for long-term management.

**Treatment**

Management focuses on the menstrual abnormalities, symptoms of androgen excess, and associated metabolic changes. Weight loss through lifestyle change, use of hormonal contraceptive agents for menstrual regulation as well as androgen suppression, antiandrogens as adjuncts for hirsutism treatment, and insulin-sensitizing agents are common components of treatment.

Lifestyle Changes

Several studies have shown that comprehensive lifestyle programs for overweight and obese women with PCOS aimed at fitness and weight loss can yield high rates of restoration of normal menstrual function, reduction of free androgen index, reduction in measures of insulin resistance, and improvements in serum lipids. Limited data show similar benefits from such interventions for obese adolescents with PCOS. Successful weight loss programs for adolescents with PCOS using both psychologic and nutritional counseling do result in improved menstrual function.

Hormonal Contraceptives

Combined (estrogen and progestin) hormonal contraceptive medications are considered first-line therapy for adults not desiring fertility and for adolescents (see Chapter 117). Adolescents with PCOS are at risk for unintended pregnancy; their fertility would be expected to be reduced relative to that of their peers, but they are still at risk for pregnancy.

Avoidance of hyperplastic endometrial states resulting from unopposed estrogen and management of abnormal uterine bleeding in anovulatory episodes can be accomplished with the use of combined hormonal contraceptives. The progestational component inhibits endometrial proliferation and the schedule of pill administration predictably regulates menstrual bleeding. The estrogenic component of combined oral contraceptive elevates circulating sex hormone-binding globulin, which reduces free and bioavailable testosterone levels. Both of the hormonal elements in oral contraceptives combine to suppress gonadotropin (particularly LH) stimulation of ovarian androgen production. DHEAS levels, often contributory to hyperandrogenemia in PCOS, are usually decreased by combined contraceptive use. Products with less-androgenic progestational components (drospirenone, desogestrel) may provide better relief from androgenic symptoms.

Using a product that is well tolerated in long-term use is more important than using a product with particular progestational component. Products with reduced frequency and duration of pill-free intervals can provide superior androgen suppression and a welcome decrease in frequency of bleeding episodes. Depot medroxyprogesterone acetate for contraception, endometrial protection, and androgen suppression may be a suitable alternative to combined hormonal contraceptives; it provides even more profound suppression of ovarian androgen production, but it does not elevate sex hormone-binding globulin. Low-dose progestin-only regimens (oral minipills, implantable progestational contraceptives, and progestin-releasing intrauterine devices) also provide effective endometrial protection but would be expected to provide only partial and/or inconsistent androgen suppression, would not elevate sex hormone-binding globulin, and have not been shown to be consistently helpful in regard to abnormal bleeding patterns.

Patients without the need for management of hyperandrogenic symptoms or contraception are often treated with periodic use of oral progestins to induce predictable menstrual bleeding and prevent endometrial hyperplasia and malignancy. Twelve-day courses of medroxyprogesterone acetate 10 mg daily or norethindrone acetate 5 mg daily are effective and safe for this purpose when taken every 1-2 mo.

Metformin

Metformin is a biguanide medication used to treat type 2 diabetes, its only FDA-approved indication. It has been used in a variety of settings and with differing objectives for patients with PCOS. Metformin exerts its principal effect by reducing hepatic production of glucose and limiting intestinal absorption of glucose. Studies show that a subset of women with PCOS resume regular ovulation and menses when treated with metformin, obviating the need for progesterational therapy or ovulation-induction medications to protect endometrial health. For some patients the resulting normal reproductive function is appealing regardless of interest in fertility.

Metformin reduces insulin resistance and the levels of androgens. Its extended use can reduce the likelihood of development of impaired glucose tolerance or the progression of impaired glucose tolerance to type 2 diabetes; these effects are not yet proved for patients with PCOS. It should not be used in the presence of renal or hepatic impairment. Typical dosing is 1,500-2,000 mg/day, achieved through gradual increments because gastrointestinal intolerance is common. Long-acting preparations are helpful when gastrointestinal intolerance is a problem.

The use of metformin in the treatment of PCOS depends on the patient’s goals and preference. For the treatment of hyperandrogenic symptoms, metformin effects may be modest compared to other available agents. There are no empiric data supporting the theoretical benefits of long-term use of metformin in adolescents with PCOS and obesity compared to the outcomes achieved with weight loss and oral contraceptive medications. Use of metformin as a first-line agent is favored by some experts, in part for improvement in serum measures of intermediate outcomes, and in part because of evidence in other populations of reduced progression of insulin resistance. There is no evidence for long-term benefit to clinical outcomes of adding metformin to treatment for women managed primarily with oral contraceptives. For adolescents receiving metformin as a first-line medication, progesterational management (combined contraceptives or periodic progestins) will still be necessary for those not resuming ovulatory function and oral contraceptives may still be an important adjunct for management of clinical hyperandrogenism and/or contraception.

Antiandrogens

Antiandrogenic medications may be added to other therapies or used alone for the treatment of hirsutism. These agents are usually used integrally or adjunctively with ovarian hormonal suppression, in part because of better reduction in hirsutism when antiandrogens are combined with ovarian suppression but also to reduce the risk of unintended embryonic or fetal exposure. The highly active androgen antagonist and progestin, cyproyterone, is available in Europe and in Canada as a single agent for treatment of hirsutism or in combination with ethinyl estradiol as an oral contraceptive with enhanced antiandrogenic profile. In the United States, spironolactone is the most commonly used antiandrogen. Spironolactone antagonizes androgens at their receptor and also impairs androgen synthesis. Doses of 100-200 mg daily are commonly used. Other agents that have been studied are finasteride, a 5α-reductase inhibitor, and flutamide, a nonsteroidal and highly specific androgen receptor antagonist. These are
rarely used because of lack of evidence of superior effectiveness, cost, and, in the case of flutamide, the potential for hepatotoxicity.

**HIRSUTISM**

Hirsutism is defined as abnormally increased terminal (mature, heavy, dark) hair growth in areas of the body where hair growth is normally androgen dependent (see Chapter 662). Its presence is a result of the combination of extent of androgenic stimulation and familial regional follicle sensitivity to androgens, which varies considerably among ethnic groups. Patients' cosmetic concerns generally determine whether findings of hirsutism are a matter for clinical investigation and treatment. Hirsutism as an isolated finding is to be distinguished from masculinization. The latter includes alteration in muscle mass, clitoral enlargement, and voice change, generally manifesting as a rapid evolution (over months). Masculinization mandates a search for neoplastic source of androgen. Elevations of testosterone or DHEAS commonly indicate an ovarian or adrenal androgen source, respectively; specific imaging and occasionally selective catheterization studies are indicated.

Hirsutism without masculinization is common. The potential causes to consider are PCOS (when there is hyperandrogenism and anovulation), benign functional androgen excess (measurable hyperandrogenism without anovulation), idiopathic hirsutism (increased hair in androgen-dependent areas without measurable androgen excess), and adult-onset adrenal hyperplasia (Table 552-4). Patients can be primarily distinguished by evidence of ovulatory disorder by menstrual history, and for those with absent or irregular menses, a diagnosis of PCOS can be made. The remainder, for whom adult-onset adrenal hyperplasia and PCOS have been excluded, either have normal androgen levels with enhanced end-organ sensitivity owing to familial or ethnic predisposition or have a functional and benign overproduction of ovarian androgens. Measures of androgens (testosterone, DHEAS) may be normal or mildly elevated in the latter group. Testosterone suppresses circulating sex-steroid binding globulin, so states of testosterone overproduction might not be accompanied by elevated measures of total testosterone, although estimates of “free” or “bioavailable” testosterone reveal hyperandrogenism. Measures of unbound testosterone distinguish idiopathic hirsutism from mild benign hyperandrogenic states; making this distinction contributes little to patient management and adds cost. Idiopathic hirsutism (without evidence of androgen excess) usually responds to antiandrogen or androgen suppression therapy similarly to hirsutism associated with elevated androgens and anovulation (PCOS), and benign hyperandrogenism not associated with PCOS.

If hirsutism is present, and clinical evaluation excludes neoplasm, adult-onset adrenal hyperplasia, and Cushing syndrome, then management for symptoms for hyperandrogenism (regardless of whether measures of circulating androgens are elevated or not) can proceed as for patients with PCOS. Estrogen and progestin suppression of ovarian function, with or without added antiandrogen treatment, is the mainstay of therapy for these patients. Androgen suppression and/or antagonism results in gradual regression of the size and productivity of follicles in androgen-sensitive areas of the face and body, and these changes will evolve over successive and months-long generations of hair growth and shedding. Patients should therefore be advised that the effects of medical therapy accrue slowly, over many months.

Bibliography

After injuries, cancer is the second most common cause of death in adolescents. Although rare, gynecologic malignancies can be followed by infertility, depression, and poor self-image, which may be lifelong.

The most common type of gynecologic malignancy found in children and adolescents is of ovarian origin and usually manifests as an abdominal mass, which must be distinguished from other organ-based tumors and ovarian functional, physiologic, inflammatory/infectious, or pregnancy-related processes. Ovarian neoplasms constitute 1% of all childhood malignancies, but account for 60-70% of all gynecologic malignancies in this age group. Approximately 10-30% of all childhood or adolescent ovarian neoplasms are malignant. Less often, the vagina or cervix is a site of malignant lesions in children, with a few specific tumors having their greatest incidence within this population. Cervical dysplasia can occur in adolescents, and healthcare providers need to be aware of current screening guidelines as well as updates on preventive measures. Vulvar malignancies in children and adolescents are exceedingly rare.

**IMPACT OF CANCER THERAPY ON FERTILITY**

Chemotherapy and radiation therapy are associated with acute ovarian failure and premature menopause (Table 553-1). Risk factors include...
older age, abdominal or spinal radiation, and certain chemotherapeutic drugs, such as alkylating agents (cyclophosphamide, busulfan). Uterine irradiation is associated with infertility, spontaneous pregnancy loss, and intrauterine growth restriction. Decreased uterine volume has been noted in girls who received abdominal radiation. The vagina, bladder, ureters, urethra, and rectum can also be injured by radiation. Vaginal shortening, vaginal stenosis, urinary tract fistulas, and diarrhea are important side effects of pelvic irradiation for pelvic cancers. Pregnancy outcomes appear to be influenced by prior chemotherapy and radiation treatment; 15% of childhood cancer survivors have infertility. Cancer survivors have an increased rate of spontaneous abortions, premature deliveries, and low birthweight infants compared to their normal healthy siblings. No data support an increased incidence of congenital malformations in offspring.

Childhood cancer survivors require extensive counseling about these specific future health implications. As part of informed consent

for cancer therapy, the possibility of infertility should be discussed with young patients and their families. Counseling and embryo or mature oocyte cryopreservation for postpubertal females before gonadotoxic therapy should be offered as standard of care. Cryopreservation of ovarian tissue for prepubertal children remains experimental and may be offered as part of a research protocol. Premature ovarian insufficiency is associated with an increased risk for cardiovascular complications, osteoporosis, and difficulties with sexual function. Risks and benefits of hormonal therapy need to be addressed.

**OVARIES**

**Neonatal and Pediatric Ovarian Cysts**

Normal follicles or physiologic ovarian cysts are seen by ultrasound examination of the ovaries in all healthy prepubertal girls. Most of these are <1 cm in diameter and not pathologic. In the neonatal period, physiologic follicular cysts as a result of maternal estrogen stimulation usually resolve spontaneously and may be followed with serial ultrasounds in the asymptomatic child. Children with an ovarian mass might have no symptoms and the mass may be detected incidentally or during a routine examination. Other children present with abdominal pain that may be accompanied by nausea, vomiting, or urinary frequency or retention. The cyst’s most common complication, ovarian torsion, can result in loss of the ovary (autoamputation of the ovary has been documented to occur antenatally). Successful reports of antenatal aspiration and postnatal laparoscopic treatment exist. Large cysts (>4-5 cm), with some complex characteristics, or any ovarian cyst in premenarchal girls with associated signs or symptoms of hormonal stimulation deserve prompt evaluation. The incidence of ovarian cysts increases again with puberty.

**Functional Cysts**

Hemorrhagic cysts are an expected part of follicular development during the menstrual cycle. Normally, a dominant follicle forms and increases in size. Following ovulation, the dominant follicle becomes a corpus luteum that, if it bleeds, is termed a hemorrhagic corpus luteum. These can become symptomatic owing to size or peritoneal irritation from blood, and they have a characteristic complex appearance on ultrasound. Expectant management for a presumed functional or hemorrhagic cyst is appropriate. Physiologic cysts are usually ≤5 cm and resolve over the course of 6-8 wk during subsequent ultrasound imaging. Monophasic oral contraceptives can be used to suppress follicular development to prevent formation of additional cysts.

**Teratomas**

The most common neoplasm in adolescents is the mature cystic teratoma (dermoid cyst). Most are benign and contain mature tissue of ectodermal (skin, hair, sebaceous glands), mesodermal, or endodermal origin. Occasionally, well-formed teeth, cartilage, and bone are found. Calcification on an abdominal radiograph is often a hallmark of a benign teratoma. These tumors may be asymptomatic and found incidentally, or they can manifest as a mass or with abdominal pain (associated with torsion or rupture). If the major component of the dermoid is thyroid tissue (struma ovarii), hyperthyroidism can be the clinical presentation. Benign teratomas should be carefully resected, preserving as much normal ovarian tissue as possible. Oophorectomy (and salpingo-oophorectomy) for this benign lesion is excessive treatment. During surgery, both ovaries should be evaluated, and if there is any question about the nature of the lesion, the specimen should be evaluated by a pathologist. An association of dermoid tumors with neural elements and anti-N-methyl-d-aspartase receptor encephalitis has been reported. Excision of the ovarian tumor has led to improvement in neurologic symptoms in some patients.

**Immature teratoma** of the ovary is an uncommon tumor, accounting for <1% of ovarian teratomas. In contrast to the mature cystic teratoma, which is encountered most often during the reproductive years but occurs at all ages, the immature teratoma has a specific age incidence, occurring most commonly in the 1st 2 decades of life. By definition, an immature teratoma contains immature neural elements. Because the lesion is rarely bilateral in its ovarian involvement, the present method of therapy consists of unilateral salpingo-oophorectomy with wide sampling of peritoneal implants.

**Cystadenomas**

Serous and mucinous cystadenomas are the second most common benign ovarian tumor. These cystic lesions can become very large, yet with care, the tumor can be resected, preserving normal ovarian tissue for future reproductive potential. The principal clinical symptoms in adolescents consist of severe menstrual pain and pelvic pain. Endometriomas (chocolate cysts) form when the ovaries are involved and are collections of old blood and hemosiderin within an endometrium-lined cyst. They have a typical homogeneous echogenic appearance on ultrasound and are more common in adults than in adolescents. Conservative management (suppressing therapy with ovulation suppression, and nonsteroidal antiinflammatory drugs) and ovarian cystectomy with preservation of as much functioning ovary as possible is recommended for adolescents.

**Endometriomas**

Endometriosis is a syndrome defined by the presence of ectopic endometrial tissue usually located within the peritoneum and abdomen. The principal clinical symptoms in adolescents consist of severe menstrual pain and pelvic pain. Endometriomas (chocolate cysts) form when the ovaries are involved and are collections of old blood and hemosiderin within an endometrium-lined cyst. They have a typical homogeneous echogenic appearance on ultrasound and are more common in adults than in adolescents. Conservative management (suppressive therapy with ovulation suppression, and nonsteroidal antiinflammatory drugs) and ovarian cystectomy with preservation of as much functioning ovary as possible is recommended for adolescents.

**Pelvic Inflammatory Disease and Tuboovarian Abscess**

Pelvic inflammatory disease complicated by a tuboovarian abscess should be considered in a sexually active adolescent with an adnexal mass and pain on examination (see Chapter 120). These patients also typically exhibit fever with leukocytosis and cervical motion tenderness. Treatment consists of administration of intravenous antibiotics. If the lesion persists or is refractory to antibiotics, drainage of the pelvic abscess by interventional radiology should be considered.

**Adnexal Torsion**

Adnexal torsion of the ovary and/or fallopian tube can occur in children or adolescents with normal adnexa or more often those enlarged by cystic (follicular, tubal) changes or ovarian (teratoma, cystadenoma) neoplasms. When torsion occurs, the venous outflow is obstructed first, and the ovary swells and becomes hemorrhagic. Once the arterial flow is interrupted, necrosis begins. It is not known how long torse adnexa will remain viable. When a female patient presents with acute lower abdominal pain, either episodic or constant, and if imaging studies shows unilateral enlargement of an adnexa, the diagnosis of adnexal torsion must be considered and acted upon. The sonographic presence of Doppler flow does not exclude the diagnosis of torsion. Prompt surgical intervention (laparoscopic detorsion) is warranted if clinical suspicion is high. Detorsion of the adnexa and observation for viability is recommended, with excision only for obviously nonviable necrotic tissues. Recovery of ovarian function after detorsion has been reported with identification of normal follicle development. Oophorectomy (plication) of the affected and the contralateral adnexa remains controversial.

**Ovarian Carcinoma**

Ovarian cancer is very uncommon in children; only 2% of all ovarian cancers are diagnosed in patients younger than 25 yr old. The Surveillance, Epidemiology, and End Results (SEER) incidence rates are ≤0.8/100,000 at age 0-14 yr and 1.5/100,000 at ages 15-19 yr. Germ cell tumors are the most common and originate from primordial germ cells that then develop into a number of heterogeneous tumor types including dysgerminomas, malignant teratomas, endodermal sinus tumors, embryonal carcinomas, mixed cell neoplasms, and gonadoblastomas. Immature teratomas and endodermal sinus tumors are more aggressive malignancies than dysgerminomas and occur in a significantly higher proportion of younger girls (younger than 10 yr of age). Sexcord stromal tumors are more common among adolescents (Table 553-2). Tumor markers such as α-fetoprotein, carcinoembryonic antigen, and the antigen CA-125 are also used for diagnosis and treatment surveillance (Table 553-3).

AFP, α-fetoprotein; CA-125, cancer antigen 125; DHEA, dehydroepiandrosterone; E2, estradiol; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; T, testosterone, MIS, müllerian inhibiting substance; VEGF, vascular endothelial growth factor.

Treatment is surgical excision followed by postoperative chemotherapy that usually consists of bleomycin, etoposide, and cisplatin. Radiotherapy is sometimes administered for disease recurrence in dysgerminomas, but it is otherwise not included in routine treatment. Staging at the beginning of therapy is of the utmost importance. In rare cases, a second-look laparotomy may be indicated for neoplasms with teratomatous elements or for those incompletely resected.

Epithelial ovarian cancers account for 19% of ovarian masses in the pediatric population, with a total of 16% being malignant. These tumors manifest almost exclusively after puberty. Common presenting symptoms include dysmenorrhea, abdominal pain, abdominal distention, nausea and vomiting, and vaginal discharge. Tumors of low malignant potential are common in adolescents and account for 30% of epithelial ovarian cancers in this age group. Given the young age of this population, although not the standard of care for adult patients, consideration may be given to conserving the contralateral ovary and uterus if they appear normal. Data suggest that in patients with early-stage disease, such an approach with appropriate surgical staging results in optimal outcomes. Overall 5 yr survival rates are approximately 73%. The number of term pregnancies and use of oral contraceptives decrease the risk of invasive epithelial ovarian cancer. Young women with a family history of ovarian cancer should seriously consider using long-term oral contraceptives for the preventive benefits when pregnancy is not being sought.

UTERUS

Rhabdomyosarcomas are the most common type of soft-tissue sarcoma occurring in patients younger than 20 yr of age (see Chapter 500). They can develop in any organ or tissue within the body except bone, and roughly 3% originate from the uterus or vagina. Of the various histologic subtypes, embryonal rhabdomyosarcomas in the female patient most often occur in the genital tract of infants or young children. They are rapidly growing entities that can cause the tumor to be expelled through the cervix, with subsequent complications such as uterine inversion or large cervical polyps. Irregular vaginal bleeding may be another presenting clinical symptom. They are defined histologically by the presence of mesenchymal cells of skeletal muscle in various stages of differentiation intermixed with myxoid stroma.
Treatment recommendations are based on protocols coordinated by the Intergroup Rhabdomyosarcoma Study Group and consist of a multimodal approach including radiation therapy and chemotherapy. Vincristine, Adriamycin, and cyclophosphamide with or without radiation therapy are the first line of treatment. Rejection rates are now very low; chemotherapy with restrictive surgery has enabled many patients to retain their uterus while achieving excellent long-term survival rates.

Leiomyosarcomas and leiomyomas are extremely rare, occurring in <2 in 10 million individuals within the pediatric/adolescent age group, although their numbers are increasing among pediatric patients with AIDS. They usually involve the spleen, lung, or gastrointestinal tract, but they could also originate from uterine smooth muscle. Pathogenesis is thought to correlate with the Epstein-Barr virus (see Chapter 254). Despite treatment that demands complete surgical resection (and chemotherapy for the sarcomas), they tend to recur frequently.

Endometrial stromal sarcoma and endometrial adenocarcinoma of the uterine corpus are extremely rare in children and adolescents, with only case reports noted in the literature. Vaginal bleeding not associated with sexual precocity is a common presenting sign. Treatment consists of hysterectomy, with removal of the ovaries, followed by adjunctive radiotherapy and/or chemotherapy, depending on the operative findings.

VAGINA

Sarcoma botryoides is a variant of embryonal rhabdomyosarcoma that occurs most commonly in the vagina of pediatric patients. Sarcoma botryoides tends to arise in the anterior wall of the vagina and manifests as a submucosal lesion that is grape-like in appearance; if located at the cervix it would resemble a cervical polyp or polypoid mass. These lesions were formerly treated with exenterative procedures; equal success has occurred with less-radical surgery (polypectomy, conization, and local excision) and adjuvant chemotherapy with or without radiotherapy. A combination of vincristine, actinomycin, and cyclophosphamide appears to be effective. Outcomes depend on tumor size, extent of disease at time of diagnosis, and histologic subtype. The 5-year survival rates for patients with clinical stages I-IV were 83%, 70%, 52%, and 25%, respectively.

Vaginal adenosis can lead to the development of clear cell adenocarcinoma of the vagina in females exposed to diethylstilbestrol in utero. Pregnant women at risk for miscarriage are no longer exposed to diethylstilbestrol, and thus fewer adolescent girls and young women are at risk for this unusual tumor.

A rare tumor occurring in the vagina of infants is the endodermal sinus tumor. This disease usually occurs in children younger than 2 yr of age, and survival rates are poor. Combination surgery and chemotherapy are appropriate. Benign papillomas can arise in the vagina of children and result in vaginal bleeding. Rarely, vaginal bleeding is secondary to leukemia or a hemangioma.

VULVA

Any questionable vulvar lesion should be biopsied and submitted for histologic examination. Lipoma, liposarcoma, and malignant melanoma of the vulva have been reported in young patients. The most common lesion is likely condyloma acuminata, associated with the human papilloma virus (HPV) (see Chapter 266). Diagnosis is usually made by visual inspection. Treatment consists of observation for spontaneous regression, topical trichloroacetic acid, local cryotherapy, electrocautery, excision, and laser ablation. Some products used to treat skin lesions in adults have not been approved for children, including provider application of podophyllin resin and home application of imiquimod, podofilox, and sinecatechins ointment.

CERVIX

Cervical cancer screening has been cytology based using the Papanicolaou (Pap) test and Bethesda Classification System (Table 553-4). Advances in epidemiologic research and molecular techniques have allowed the identification of the integral role of HPV in development of cervical cancer. HPV has become an important factor in the interpretation of cytologic results and subsequent management. The discovery of HPV presents a unique target for cervical cancer prevention, with the pediatric and adolescent population at the forefront of its implementation. Two HPV vaccines (bivalent HPV2 and quadrivalent HPV4) are currently available to protect against cervical cancer, and the HPV4 vaccine also protects against genital warts and cancers of the anus, vagina, and vulva. HPV vaccines offer the best protection if all three vaccine doses are administered before the patient is ever sexually active. The American Congress of Obstetrics and Gynecology recommends vaccination for all girls and women ages 9-26 yr, and The Advi-

The Advisory Committee on Immunization Practices (http://www.cdc.gov/vaccines/schedules/hcp/index.html) recommends routine vaccination of girls ages 11-12 yr with 3 doses of quadrivalent HPV vaccine, starting as early as age 9 yr. Catch-up vaccination is indicated for girls and women ages 13-26 yr who have not been fully vaccinated. Female patients should be vaccinated even if sexually exposed; vaccination prior to exposure is ideal. Pap testing and screening for HPV DNA or HPV antibody is not required before vaccination. The American Congress of Obstetrics and Gynecology recommends that cervical cancer screening of women who have been immunized against HPV-16 and HPV-18 should not differ from that of nonimmunized women and should follow the exact same regimen.

The adolescent population presents a unique challenge to cervical cancer screening, because the prevalence of HPV is high. In adolescents ages 15-19 yr, HPV cumulative incidence rates after initiation of sexual activity are reported as 17% at 1 yr and 35.7% at 3 yr. Correlating with the natural history of an HPV infection, >90% of low-grade intraepithelial lesions regress within this age group, giving the presence of HPV in this population little clinical significance. The overall incidence of a high-grade lesion on Pap test in the adolescent population remains low (0.7%); cervical cancer is uncommon in the age group. In the United States, the Surveillance, Epidemiology, and End Results Cancer Statistics Review 1975-2006 published by the National Cancer Institute reports an incidence of invasive cervical cancer as 0.1/100,000 in 15-19 yr olds, with no cases reported before the age of 15 yr; similar rates (≤0.3 cases per 100,000 among women ages 15-19 yr) have been reported by the Canadian Cancer Registry. Therefore, colposcopy for minor cytologic abnormalities within this age group should be highly discouraged, because it will result more often in harm than produce any clinical benefit. The American Society for Colposcopy and Cervical Pathology and the American College of Obstetricians and Gynecologists guidelines recommend that adolescents should be managed conservatively and should not receive Pap smear screening until age 21 yr regardless of age of onset of sexual intercourse. If an HPV test is done, the results should be ignored. However, sexually active immunocompromised (HIV-positive patients or organ transplant recipients) adolescents should undergo screening twice within the 1st yr after diagnosis and annually thereafter. Table 553-4 demonstrates management recommendations for abnormal cytologic results for adolescents who are screened in error and immunocompromised sexually active adolescents who are screened. Routine screening for cervical cancer in the general adolescent population (younger than age 21 yr) is not recommended.

Clinic protocols that require teenagers to undergo Pap smears before prescribing contraceptives should be reconsidered in light of these recommendations.

EMBRYOLOGY
Cellular differentiation, duct elongation, fusion, resorption, canalization, and programmed cell death are all involved in the sequence of events that occur in a developing embryo and early fetus to create a normal reproductive system. Myriad gonadal, müllerian, and/or vulvovaginal anomalies can result from interruption of the intricate sequence or functions of any one of these processes during formation of the reproductive system (Table 554-1). Genetic, epigenetic, enzymatic, and environmental factors all have some role in the process (Table 554-2).

Phenotypic sexual differentiation, especially during formation of the vulvovaginal and müllerian systems, is determined from genetic (46,XX), gonadal, and hormonal influences (see Chapter 582). The genetic sex of the embryo is determined at fertilization when the gamete pronuclei fuse. The primordial germ cells (oogonia or spermatogonia) migrate from the yolk sac to the gonadal ridges. The primitive gonads are indistinguishable until about the 7th wk of development. Gonadal development determines the progression or regression of the genital ducts and subsequent hormonal production and, thus, the external genitalia. Critical areas in the SRY region (sex-determining region on the Y chromosome) are believed to be the factors that drive the development of a testis from a primitive gonad as well as spermatogenesis. The testis begins to develop between 6 and 7 wk of gestation, first with Sertoli cells followed by Leydig cells, and testosterone production begins at approximately 8 wk of gestation. The genital tract begins to differentiate later than the gonads. The differentiation of the Wolffian ducts begins with an increase in testosterone, and the local action of testosterone activates development of the epididymis, vas deferens, and seminal vesicle. Further male genital duct and external genital structures depend on the conversion of testosterone to dihydrotestosterone.

In a 46,XX embryo, female sexual differentiation occurs about 2 wk later than gonadal differentiation in the male. Because the ovaries develop prior to and separately from the müllerian ducts, females with müllerian ductal anomalies usually have normal ovaries and steroid hormone production. The regression of the Wolffian ducts results from the lack of local gonadal testosterone production, and the persistence of the müllerian (or paramesonephric) ducts results from the absence of antimüllerian hormone (or müllerian-inhibiting substance) production. The müllerian ducts continue to differentiate into the fallopian tubes, uterus, and upper vagina without interference from antimüllerian hormone. There are complex interactions among the mesonephric, paramesonephric, and metanephric ducts early in embryonic development, and normal development of the müllerian system depends on such interaction. If this process is interrupted, coexisting müllerian and renal anomalies are often discovered in the female patient at the time of evaluation. Differentiation along the female pathway is often referred to as the default pathway, but it is an extremely intricate process regulated by the absence, presence, or dosage compensation of numerous gene products (i.e., SRY, SF-1, WTI, SOX9, Wnt-4, GATA4, DAX-1, BMP4, HOX genes) and remains not entirely understood.

By 10 wk of gestation, the caudal portions of the müllerian ducts fuse together in the midline to form the uterus, cervix, and upper vagina, in a Y-shaped structure, with the open upper arms of the Y forming the primordial fallopian tubes. Initially the müllerian ducts are solid cords that gradually canalize as they grow along and cross

the mesonephric ducts caudally and fuse in the midline. The mesonephric ducts caudally open into the urogenital sinus, and the müllerian ducts contact the dorsal wall of the urogenital sinus, where proliferation of the cells at the point of contact form the müllerian tubercle. Cells between the müllerian tubercle and the urogenital sinus continue to proliferate, forming the vaginal plate. At the same time of the midline fusion of the müllerian ducts, the medial walls begin to degenerate and resorption occurs to form the central cavity of the uterovaginal canal. Uterine septal resorption is thought to occur in a caudal to cephalad direction and to be complete at approximately 20 wk of gestation. This theory has been scrutinized because some anomalies do not fit the standard classification system. It is possible that septal resorption starts at some point in the middle and proceeds in both directions. At approximately 16 wk of gestation the central cells of the vaginal plate desquamate and resorption occurs, forming the vaginal lumen. The lumen of the vagina is initially separated from the urogenital sinus by a thin hymenal membrane. The hymenal membrane undergoes apoptosis and central resorption and is usually perforate before birth.

**Epidemiology**

Müllerian anomalies can include abnormalities in portions or all of the fallopian tubes, uterus, cervix, and vagina (Fig. 554-1). True estimates of prevalence are difficult because of the varied presentations and asymptomatic nature of some of the anomalies. Imaging techniques have made significant contributions to uterovaginal anomaly diagnoses, which has increased reporting of anomalies and led to additional combinations of anomalies. Most estimate that müllerian anomalies are present in 2-4% of the female population. The incidence increases in women with a history of adverse pregnancy outcomes or infertility: 5-10% of infertile women undergoing hysterosalpingogram, 5-10% of women with recurrent pregnancy loss, and 25% or more of women with late miscarriages and/or preterm delivery have müllerian defects.

**Clinical Manifestations**

Vulvovaginal and müllerian anomalies can manifest at a variety of chronological time points during a female’s life: from infancy, through childhood and adolescence, and adulthood (see Table 554-1). The majority of external genitalia malformations manifest at birth, and often even subtle deviations from normal in either a male or female newborn warrant evaluation. Structural reproductive tract abnormalities can be seen at birth or can cluster at menarche or any time during a woman's reproductive life. Some müllerian anomalies are asymptomatic, whereas others can cause gynecologic, obstetric, or infertility issues.

Clinical manifestations and treatments depend on the specific type of müllerian anomaly and are varied. There may be a pelvic mass, which may or may not be associated with symptoms. A mass bulging at the introitus or within the vagina indicates complete or partial

**Figure 554-1** Classification system of müllerian duct anomalies developed by the American Fertility Society. *(From Gholoum S, Puligandla PS, Hui T, et al: Management and outcome of patients with combined vaginal septum, bifid uterus, and ipsilateral renal agenesis [Herlyn-Werner-Wunderlich syndrome]. J Pediatr Surg 41:987–992, 2006, Fig. 3.)*
outflow tract obstruction. An adolescent can present with pelvic pain either in association with primary amenorrhea or several months after the onset of menarche. Patients also may be asymptomatic until they present with miscarriage, pregnancy loss, or preterm delivery. When presentation is acutely symptomatic, emergency management may be required. Obstruction can result from a number of distinct anomalies including an imperforate hymen, transverse vaginal septum, and noncommunicating rudimentary horn. As menstrual fluid accumulates proximal to the obstruction, the resulting hematocolpos and hematometra cause cyclic pain or a pelvic mass. Prenatal or neonatal presentation of hydrometrocolpos from distal vaginal obstruction produces fluid accumulation in the vagina and uterus and presents as a lower abdominal mass with or without associated acute urinary tract obstruction. Hydrometrocolpos with polydactyly may be a result of 2 disorders: McKusick-Kaufman syndrome (with associated congenital heart disease) and Bardet-Biedl syndrome (with obesity, learning disabilities, retinitis pigmentosa, renal anomalies). Both are autosomal recessive disorders.

Adolescent patients can present with acute obstruction of the outflow tract because of a müllerian anomaly, which requires emergency evaluation and surgical treatment. A small percentage of girls present with concomitant urinary retention caused by an altered urethral angle or pressure on the sacral plexus. Urinary hesitancy and incomplete emptying symptoms may be present before abdominopelvic pain from the obstruction in a patient of any age.

LABORATORY FINDINGS
Several radiographic studies have been used, often in combination, to aid in diagnosis including ultrasound, hysterosalpingogram, sonohysterography (saline-infusion sonography), and MRI. Laparoscopy and hysteroscopy were the gold standard for evaluation of müllerian anomalies, but the new standard may be MRI because of its noninvasive, high-quality capabilities. MRI is the most sensitive and specific imaging technique used for evaluating müllerian anomalies because it can image nearly all reproductve structures, blood flow, external contours, junctional zone resolution on T2-weighted images, and associated renal and other anomalies. MRI also has a high correlation with surgical findings because of its multiplanar capabilities and high spatial resolution. Three-dimensional ultrasound is another useful diagnostic tool and may be superior to traditional pelvic ultrasound and hysterosalpingogram. Three-dimensional ultrasound and MRI results are highly concordant in the diagnosis of uterine malformations. Evaluation of the external contour of the uterus is important for differentiating types of uterine anomalies. This often requires a combination of radiologic modalities for uterine cavity, external contour, and possible tubal patency. Diagnostic laparoscopy or hysteroscopy may be necessary depending on the presentation, but it is used less with the advance ment of MRI and other imaging.

Diagnosis of müllerian anomalies should include a physical exam, pelvic ultrasound, possibly MRI, and renal and skeletal inspections for associated anomalies. Renal anomalies are noted in 30-40% and skeletal anomalies are associated in 10-15% of patients with müllerian anomalies. Unilateral renal agenesis occurs in 15% of patients. The most common skeletal anomalies are vertebral. Patients usually have a normal female karyotype (46,XX), but several familial segregations and gene mutations and/or abnormal karyotypes have been reported (see Table 554-2). Approximately 5-8% of patients with congenital müllerian anomalies have abnormal karyotypes. Most malformations are sporadic, with a polygenic mechanism and multifactorial etiology.

UTERINE ANOMALIES
Anomalous development of the uterus may be symmetric or asymmetric and/or obstructed or nonobstructed. Patients can present with primary amenorrhea or have either irregular or regular menstrual cycles. There may be an asymptomatic pelvic mass or dysmenorrhea. In adolescents and adults, pregnancy loss can cause the first suspicion of a uterine anomaly. Treatment is highly specific to the specific anomaly.

SEPTATE UTERUS
A uterine septum is the most common of all müllerian anomalies, accounting for just over half of all abnormalities, and it is the most common structural uterine anomaly. After the 2 müllerian ducts fuse in the midline, resorption must occur to unify the endometrial cavities; failure of this process results in some degree of uterine septum. It can vary in length from just below the fundus to beyond the cervix, depending on the amount of caudal resorption. A septate uterus has a normal external uterine contour, which is what distinguishes it from a bicornuate or didelphic uterus. An MRI can help delineate between a predominantly fibrous septum and a muscular or myometrial septum. Because the septum may be poorly vascularized, a septate uterus is the most significant anomaly associated with pregnancy loss, as well as other untoward pregnancy outcomes. Hysteroscopic metroplasty (septal excision) is generally recommended in the setting of a previous pregnancy loss. Controversy still exists regarding whether a woman should have such a surgical procedure without a setting of a previous pregnancy loss. Correction of uterine septum improves the prognosis in patients with a history of adverse obstetrical outcomes (i.e., spontaneous abortions, preterm delivery). The length of the septum might not correlate with the frequency or occurrence of untoward pregnancy outcomes. Differentiating precisely between bicornuate and septate uteri is extremely important to determine effective and safe treatment plans.

Bicornuate Uterus
Both müllerian ducts develop and elongate in this anomaly, but they do not completely fuse in the midline. The vagina and external cervix are normal, but the extent of division of the 2 endometrial cavities can vary depending on the extent of failed fusion between the cervix and the fundus. Bicornuate uteri are also associated with increased preterm labor and delivery, malpresentation, and miscarriage. This anomaly accounts for approximately 10-20% of müllerian anomalies and a significant percentage of uterine anomalies.

Unicornuate Uterus and Rudimentary Horns
A unicornuate uterus results from a normal creation of a fallopian tube, functional uterus, cervix and vagina from 1 müllerian duct. The other side fails to develop, resulting in either absence of the contralateral müllerian duct or a rudimentary horn. There is a 30-40% association of renal anomalies. If a rudimentary horn is identified, it is important to determine whether functional endometrium is present (usually with T2-weighted MRI images). About two-thirds of rudimentary horns are noncommunicating, some with a fibrous band connecting the 2 structures. Rudimentary horns can also communicate with the contralateral uterus. A fertilized ovum can implant and develop within a rudimentary horn. These pregnancies are incompatibile with expectant gestation, and rupture of the horn could be life-threatening. Rupture tends to occur at a later gestation than with an ectopic pregnancy, and hemorrhage is severe. Patients with rudimentary horns with functioning endometrium can also present with pain caused by accumulating menses. Because the other horn has a normal outflow pathway, these patients present with pain, not primary amenorrhea. Pregnancies that arise in a unicornuate uterus are associated with increased preterm labor and delivery, malpresentation, and miscarriage.

Uterine Didelphys
A uterine didelphys is the result a complete failure of fusion and represents 5% of müllerian anomalies. There are 2 fallopian tubes, 2 completely separate uterine cavities, 2 cervixes, and often 2 vaginal canals or 2 partial canals because of an associated longitudinal vaginal septum (75% of the time). Evaluation for renal anomalies should be pursued because they are common as well. At times, the longitudinal septum attaches to 1 sidewall and obstructs 1 side of the vagina (or hemivagina). The combination of uterine didelphys, obstructed hemivagina, and ipsilateral renal agenesis is a variant of the broad spectrum of müllerian anomalies that is referred to as the Heryln-Werner-Wunderlich syndrome or obstructed hemivagina and ipsilateral
renal anomaly syndrome in the literature. Adolescents with this disorder usually present with abdominal pain shortly after menarche. Although there may still be a risk of adverse pregnancy outcomes with a uterus didelphys (preterm labor, malpresentation), overall pregnancy outcomes are generally good and are associated with less risk than in other uterine anomalies.

Arcuate Uterus
An arcuate uterus is a uterine cavity that has a small midline septum, from lack of a small amount of resorption, and sometimes a slight indentation of the uterine fundus. An arcuate uterus might represent a variant of normal rather than a müllerian anomaly. Untoward pregnancy outcomes are rare and surgical correction is not warranted.

Uterine Anomalies in Diethylstilbestrol-Exposed Patients
Intrauterine diethylstilbestrol (DES) exposure is associated with an increased risk for development of uterine anomalies and clear cell adenocarcinoma of the vagina and cervix. DES was used to prevent preterm delivery, but this practice was discontinued in 1971. Commonly observed uterine features associated with DES exposure include the following: T-shaped uterus, cervical hypoplasia, fallopian tube irregularities, scollopied or irregularly shaped endometrial contour, constriction bands, and others. DES suppresses and/or alters Wnt and HOX genes in mice and thus might work by affecting gene expression in müllerian duct development, causing uterine abnormalities, vaginal adenosis, and potentially carcinoma.

Treatment
Treatment depends on the specific anomaly. Hysteroscopic surgical resection is widely supported for uterine septa. If a septate uterus extends through the cervical canal, many choose to leave this cervical portion of the septum because of concerns for future incompetence, although case reports indicate that incisions have been done with uneventful follow-up. Most would support the incision of a uterine septum in the clinical setting of pregnancy loss, but some would also support prophylactic metroplasty without a history of miscarriage, especially before in vitro fertilization.

A noncommunicating horn with functional endometrium should be resected to improve quality of life or prevent future complications; opinions vary as to whether resection of a communicating horn or one with no functional endometrium is warranted. Any surgical resection of a rudimentary horn requires careful surgical technique to protect the ipsilateral ovarian blood supply and the myometrium of the remaining unicornean uterus.

Although metroplasty had been advocated with didelphys and bicornuate uteri and a history of poor pregnancy outcomes in the past, currently most clinicians feel there is not enough evidence to support such a complicated procedure. Any obstruction to the outflow tract must also be relieved; this can necessitate creation of a vaginal window or excision of a hemivaginal septum.

VAGINAL ANOMALIES
Abnormalities of the Hymen
An imperforate hymen is the most common obstructive anomaly, and familial occurrences have been reported. Its incidence is most often reported as approximately 1 in 1,000. In the newborn period and early infancy, it may be diagnosed by a bulging membrane caused by a mucocolpos from maternal estrogen stimulation of the vaginal mucosa. This can eventually reabsorb if it is not too large or symptomatic. More often it is diagnosed at the time of menarche, when menstrual fluid accumulates. The clinical manifestations often are a bulging blue-black membrane, pain, primary amenorrhea, and normal secondary sex characters. Depending on the circumstance, patients might have cyclic abdominal pain or a pelvic mass. Other hymenal abnormalities have been reported. A normal hymen can have various configurations (annular, crescentic). Some hymenal membranes do not undergo complete resorption or perforation, resulting in microperforate, cribriform, or septate-shaped hymen. Infants and children vary in age as to when these are recognized, but hymenal anomalies are often discovered after menarche when it is difficult for an adolescent to place a tampon, so resection is indicated.

Congenital Absence of the Vagina and Mayer-Rokitansky-Küster-Hauser Syndrome
Vaginal agenesis or atresia results when the vaginal plate fails to canalize. On physical exam it appears as an extremely foreshortened vagina, sometimes referred to as a vaginal dimple. Isolated (partial) vaginal agenesis involves an area of aplasia between the distal vaginal portion and a normal upper vagina, cervix, and uterus. On initial presentation it may be confused with a low transverse septum or imperforate hymen, and therefore clear delineation of the anomaly is critical before attempting surgical repair. It can also manifest with cyclic pain and a bulging mass just after menarche. Surgical repair and reconstruction are complicated and individualized and best performed with consultation of specialists.

Uterine and vaginal agenesis often occur together because of their close association during development, when müllerian duct development fails early in the process. The most common cause of vaginal agenesis is Mayer-Rokitansky-Küster-Hauser syndrome, with an incidence reported at 1 in 4,000-10,000 female births. After gonadal dysgenesis, müllerian agenesis is the second most common cause of primary amenorrhea. The cause is unknown and likely has a multigenic and multifactorial etiology. Mayer-Rokitansky-Küster-Hauser syndrome is characterized by primary amenorrhea, normal vulva, anomalies of the uterus (usually aplasia or agenesis), attenuated fallopian tubes, normal ovaries, normal female karyotype and phenotype, and associated anomalies (most commonly renal and skeletal). The vagina either is completely absent or only has a small dimpled opening. Although most patients with müllerian agenesis have small rudimentary müllerian bulbs, approximately 2-7% of patients can have active endometrium within these uterine structures. These patients will often present with cyclic pelvic pain. MRI imaging is often necessary to determine if any small uterine remnant is present (often located on the pelvic sidewall or near the ovaries and only a small fibromuscular remnant) and to clearly delineate the anomaly. Laparoscopy is not necessary to diagnosis müllerian agenesis but may be useful in the treatment of rudimentary uterine horns, particularly when removal of obstructed uterine structures or associated endometriosis is indicated for pelvic pain. Absence of the vagina and uterus has significant anatomic, physiologic, and psychologic implications for the patient and family. Any diagnosis of müllerian agenesis must be differentiated from androgen insensitivity (testicular feminization) as well; karyotype, serum testosterone levels, and pubic hair distribution usually help distinguish between the two.

Lesions involving other organ systems occur in association with the Mayer-Rokitansky-Küster-Hauser syndrome. The most common are urinary tract anomalies (15-40%) primarily involving unilateral absence of a kidney, a horseshoe or pelvic kidney, and skeletal anomalies (5-10%), which primarily involve vertebral development but can also include hearing impairment.

Longitudinal Vaginal Septa
Longitudinal vaginal septa represent failure of complete canalization of the vagina. These often occur in the presence of uterine anomalies as noted earlier.

Transverse Vaginal Septa
Vertical fusion defects can result in a transverse septum, which may be imperforate and associated with hematocolpos or hematometra in adolescents or with mucocolpos in infants. These are much less common anomalies, reportedly found in 1 in 80,000 females. Most patients present with amenorrhea and cyclical pain around the time of menarche. Patients who have a small opening in the transverse septum might present with prolonged vaginal drainage and discharge. Transverse vaginal septa vary in location in the vagina (15-20% in the lower third, but most in the middle or upper third of the vagina) and thickness but
are generally ≤1 cm thick. High locations, thick septa, and narrow vaginal orifices present challenging surgical cases.

**Transverse vaginal septa** may be associated with other congenital anomalies, although this occurs less often than with müllerian agenesis. These patients have a functional normal uterus, unlike women with Mayer-Rokitansky-Küster-Hauser syndrome. There is also an increased incidence of endometriosis secondary to retrograde menstruation.

Evaluation of transverse vaginal septa includes careful pelvic examination and often pelvic imaging, usually with MRI and ultrasound, to delineate the anatomic abnormalities. MRI is especially helpful to determine the thickness of the septum and presence of a cervix and for surgical planning. Diagnosis and treatment plans should be made as soon as possible after menarche, because significant accumulation of hematometra and/or hematosalpinx could affect future reproductive success by negatively affecting uterine and/or tubal function.

**Treatment**

An imperforate hymen requires resection to prevent or relieve the outflow tract obstruction. Many approach it with a horizontal, lunate or cruciate incision, excision of excess tissue, and reanastomosis of the mucosal edges. Repair should be done at time of diagnosis, if the patient is symptomatic. Although the lesion may be repaired any time during infancy, childhood, or adolescence, surgery is facilitated by estrogen stimulation and thus is ideally performed in adolescence, either after puberty or menarche. Variants in the hymen with microperforations or hymenal septa may interfere with tampon use and resection of this tissue is usually electively performed.

Treatment of congenital absence of the vagina is usually delayed until the patient is ready to be sexually active. The nonsurgical approach is the most common first-line therapy owing to the high success rate and extremely low morbidity. It requires dedicated use of dilators to create a functional vagina. The series of dilators come in progressively increasing sizes and require a commitment and maturity on the part of the patient to comply with daily use (20-30 min daily). If done correctly it is possible to achieve a functional vaginal length (6-8 cm), width, and physiologic angle for intercourse in about 6-8 wk of therapy. When the ultimate size that accommodates coitus is reached, then the patient must use the dilator or have coitus with a frequency that maintains adequate length.

Surgical approaches require more expertise and often some postoperative vaginal dilation to ensure a functional result. Controversy exists among surgical subspecialties, because pediatric surgeons and pediatric urologists often recommend creating the neovagina in infancy. Pediatric gynecologists and reproductive endocrinologists believe better outcomes result from creating the neovagina when the young woman is interested in sexual activity and can participate in the decision to have surgery and in her own postoperative recovery. There is no consensus as to the best surgical option; the most-used procedures include 2 surgical approaches followed by dilators or an approach using a loop of bowel out of which to construct a vagina. Patients need to be counseled about the ability to use their own oocytes and a gestational carrier through in vitro fertilization to achieve pregnancy. These therapies can be quite complicated physically and emotionally. They are best approached in a multidisciplinary fashion, often with the assistance of psychologic counseling and surgeons with specialized training.

For transverse vaginal septa, treatment is surgical resection of the obstruction through a vaginal approach. Some surgeons advocate waiting for 1 or more menstrual cycles or using preoperative dilators from below to increase the depth and circumference of the distal vagina and to allow menstrual blood to accumulate and dilate the upper portion of the vagina. Complete resection of the septum, with primary anastomosis of the upper and lower mucosal segments, should be attempted. A vaginal stent is sometimes placed postoperatively in the vagina to maintain patency and allow squamous epithelization of the upper vagina and cervix. Follow-up dilation may be necessary after the stent is removed. Careful preoperative assessment is important because surgeons who begin a case believing they are operating on an imperforate hymen can find themselves in entirely different and more complex surgical planes. Regardless of the approach, vaginoplasty is often best deferred until the patient is mature and physically and psychologically prepared to participate in the healing process and postoperative dilator treatments.

Longitudinal vaginal septa themselves do not lead to adverse reproductive outcomes but may be symptomatic in a patient, causing dyspareunia, difficulties with tampon insertion, or impedance during vaginal birth. Such complaints can warrant a resection of the vaginal septa. In a small number of patients there may be unilateral obstruction of a hemivagina, which would require incision and resection.

**CERVICAL ANOMALIES**

Congenital atresia or complete agenesis of the uterine cervix is extremely rare and often manifests at puberty with amenorrhea and pelvic pain. It is associated with significant renal anomalies in 5-10% of patients. A pelvic MRI is often warranted to completely define the abnormality. Usually, pain and obstruction are significant and a hysterectomy is necessary. Attempts to reconnect the uterus to the vagina are rarely successful and associated with significant morbidity and reoperation rates. As with most müllerian anomalies, the ovaries usually remain normal and future reproduction can still occur through the use of in vitro fertilization and a gestational carrier.

**VULVAR AND OTHER ANOMALIES**

**Complete Vulvar Duplication**

Duplication of the vulva is a rare congenital anomaly that is seen in infancy and consists of 2 vulvas, 2 vaginas, and 2 bladders, a didelphic uterus, a single rectum and anus, and 2 renal systems.

**Labial Asymmetry and Hypertrophy**

With the onset of puberty the labia minora enlarge and grow to an adult size. A woman’s labia can vary in size and shape. Asymmetry of the labia, where the right and left labia are different in size and appearance, is a normal variant. Some women are uncomfortable with what they perceive to be their asymmetric or enlarged labia minora and complain about self-consciousness and discomfort while wearing tight clothing, exercising, or having sex. The enlarged labia can have a protuberant and abnormal appearance that can be functionally or psychologically bothersome. Local irritation, problems of personal hygiene with bowel movements or menses, interference with sexual intercourse or while sitting or exercising have resulted in requests for labial reduction. Some surgeons are advertising procedures to reduce uneven or enlarged labia minora. The American College of Obstetricians and Gynecologists does not support performing such surgery unless there is significant impairment in function. Medically indicated surgical procedures can include reversal or repair of female genital cutting and treatment for labial hypertrophy or asymmetrical labial growth secondary to congenital conditions, chronic irritation, or excessive androgenic hormones. Complications of labial surgery include loss of sensation, keloid formation, and dyspareunia.

**Clitoral Abnormalities**

Agenesis of the clitoris is rare. Clitoral duplication has been reported, often associated with pelvic organ abnormalities, including agenesis of other genital tract structures and bladder exstrophy. Exposure to male hormones will result in clitoral enlargement, and is often a sign of a testosterone producing tumor or use of exogenous steroids.

**Cloacal Anomalies**

Cloacal anomalies are rare lesions representing a common urogenital sinus into which the gastrointestinal, urinary, and vaginal canals all exit. Usually there is an abnormality in all or some of the processes of fusion of the müllerian ducts, development of the sinovaginal bulbs, or development of the vaginal plate. The single opening (cloaca) requires surgical correction, preferably by a multidisciplinary pediatric surgical team.

**Ductal Remnants**

Even though the opposite duct regresses in both sexes, there can sometimes be a small portion of either the müllerian or Wolffian duct that
remains in either the male or female, respectively. Such remnants can form cysts, which is what makes them clinically visible during surgery, examination, or imaging. Most do not cause pain, although torsion of some has been reported, and small asymptomatic ones usually do not require resection. The most commonly reported are hydatid of Morgagni cysts (remnant of a wolffian duct arising from the fallopian tube), cysts of the broad ligament, and Gartner’s duct cysts, which can form an ectopic ureter or be found along the cervix or vaginal walls.

Bibliography

Adolescence presents challenges for all children and their families, but particularly so for teens with special needs and their families. The start of menstrual periods, the mood changes associated with puberty and the concerns about sexual activity with possible unplanned pregnancies, and worries about safety and abuse may present teens with disabilities and their families with additional issues.

**SEXUALITY AND SEXUAL EDUCATION**

Adolescents with special needs can have physical and/or developmental disabilities. These young women are often seen as asexual by their families, care providers, and society and therefore sexual education might not have been provided or considered necessary. Physically disabled teens are as likely to be sexually active as nondisabled teens. The care provider needs to assess the teen's knowledge of anatomy and sexuality, her social knowledge of relationships, and her ability to consent to sexual activity. Education regarding HIV and other sexually transmitted infections, disease prevention, and contraception, including postcoital contraception, should be offered at a developmentally appropriate level. Teens with disabilities may be more at risk for isolation and depression during adolescence.

**ABUSE**

The risk for sexual abuse in teens with disabilities is difficult to estimate. Screening for abuse is mandatory. Studies show that teens with physical disabilities are just as sexually active as their nondisabled counterparts but that more of their activity is nonvoluntary. Patients with cognitive impairment are often taught to be cooperative, which may make them more vulnerable. Abuse prevention education can include the No! Go! Tell! model. For teens with limited verbal capacity or developmental delay, abuse may be very hard to detect. The care provider needs to be vigilant in looking for signs on physical exam, such as unexplained bruises or scratches, or changes in behavior, such as regression, which may be indications of sexual abuse in those adolescents (see Chapters 40.1 and 119).

**PELVIC EXAMINATION**

An internal pelvic exam is rarely indicated in teens that are not sexually active, as Papanicolaou smears are not recommended to start until age 21 yr. An external genital exam can be performed, if there are vulvar issues such as discharge, irregular bleeding, suspicion for abuse, or foreign body. The frogleg position is usually favored over the use of stirrups. If the vagina or cervix needs to be clearly visualized for a medical indication, an exam under anesthesia by a gynecologist should be considered. Testing for sexually transmitted infections can be accomplished by urine testing or vaginal swabs (see Chapter 120).

**MENSTRUATION**

Irregular menstruation is common in teenagers, especially during the 1st 5 yr after menarche, because of immaturity of the hypothalamic-pituitary-ovarian axis and subsequent anovulation (see Chapter 116). Several conditions in teens with disabilities are associated with an even higher risk of irregular cycles. Teens with Down syndrome have a higher incidence of thyroid disease. There is a higher incidence of reproductive issues, including polycystic ovarian syndrome in teens with epilepsy and on certain antiepileptic drugs (see Chapter 552). Antipsychotic medication can cause hyperprolactinemia, which can affect menstruation.

For teens with disabilities the main issue with menstrual cycles, whether they are regular, irregular, or heavy, is the impact of menstruation on the patient's life, her health, and her ability to perform her normal activities. The history should focus on this aspect, and menstrual calendars may be helpful to document the cycles, behavior, and the impact of treatments. Most adolescents who self-toilet can learn to use menstrual hygiene products appropriately.

The evaluation for abnormal bleeding is the same as for all teens. Areas requiring particular attention for the girl with special needs are the consideration of menstrual suppression for hygiene or cyclical behavioral issues, like crying, tantrums, or withdrawal. A request for birth control, especially coming from a caregiver and not from the teen, requires an evaluation of the teen's ability to consent to sexual activity and evaluate the safety of her environment. Guidelines for abnormal bleeding include menses that are too heavy (in excess of 1 pad/hr for several hours in a row), too long (longer than 10 days), or too frequent (fewer than 20 days apart).

**Treatment of Menstruation**

If after documenting the impact of the regular or irregular cycles on the patient's well-being (often through menstrual or behavioral charting for several months), the care provider, patient, and family decide on menstrual intervention, several options are available. Menstrual regulation is not different from that in the nondisabled teenager in general, although there are some special considerations. Goals for treatment can be to decrease the heaviness of flow, regulate cycles to predictable bleeding, relieve pain or cyclical behavior symptoms, provide contraception, and/or obtain amenorrhea. Menstrual suppression leading to complete amenorrhea is usually difficult to obtain and infrequent scheduled bleeds may be easier to manage than unpredictable spotting, a common side effect of any suppressive treatment, for certain patients. After treatment has started, continue to monitor cycles, ideally with continued menstrual or behavior calendars.

**Nonhormonal Methods**

If menorrhagia or dysmenorrhea (occasionally leading to cyclical behavior changes in nonverbal teens) is the main concern, the patient can be started on nonsteroidal antiinflammatory drugs. These can decrease the flow by up to 20% in adequate doses and can be used alone or in combination with other treatments.

**Estrogen-Containing Methods**

**Oral Contraceptives**

Cyclical oral contraceptives usually lead to regular, lighter cycles with less cramping. Extended cycling through the use of continuous use of oral contraceptives can suppress cycles, with amenorrhea rates improving with time. Some unpredictable spotting is usually unavoidable, and often teens with special needs prefer to have predictable cycles several times a year. A chewable oral contraceptive is available for those with swallowing issues.
Contraceptive Ring
The contraceptive ring is usually used in a pattern of 3 wk on and 1 wk off, but it can be used (off-label) in a continuous 4-wk pattern, which can lead to less bleeding. However, the contraceptive ring may be difficult to use for a teen with dexterity problems and help with placement has obvious privacy issues.

Contraceptive Patch
The weekly patch can also be used in a continuous fashion. Some teens with developmental disabilities remove their patch erratically, and placement out of reach (e.g., on buttocks or shoulder) is advised.

Estrogen Use, Venous Thromboembolism and Mobility Issues
Immobility per se is not a contraindication to estrogen-containing contraceptives, according to the Centers for Disease Control and Prevention medical eligibility criteria for contraception released in 2010. There are some data to support the concern that higher-dose oral estrogen, the combined estrogen patch, and the newer progestin preparations may have a higher risk for venous thromboembolism. However, there are minimal data on the risk of venous thromboembolism in teens with mobility issues in wheelchairs with or without extraneous estrogen. It is important to obtain a thorough and extended family history for hypercoagulability before initiating estrogen therapy. Careful use of lower-dose (30 or 20 µg) ethinyl estradiol preparations may be advisable and third-generation progestin combinations and the patch should only be used if other methods have failed.

Progestin-Only Methods

Intramuscular Medroxyprogesterone Acetate
Intramuscular medroxyprogesterone acetate (DMPA) has long been used for menstrual suppression. Two issues are particularly relevant to teens with disabilities. Studies documenting a decrease in bone density associated with longer-term use of DMPA and a black box warning by the FDA have raised concerns about use of these products in young women, although research indicates that bone density improves after the medication is stopped. For teens with mobility issues or those with very low body weight who are already at risk for low bone density, decreased bone density is a real concern, although the risk of fractures is unclear. Adequate calcium and vitamin D is recommended. The second issue for teens with mobility issues is weight gain associated with DMPA, especially among obese teens, which can lead to transfer and mobility issues. If long-term DMPA is considered for a specific patient, calcium and vitamin D supplementation is recommended and bone density could be measured after several years of use, and weight should be monitored closely.

Oral Progestins
Continuous oral progestins can also be very effective to obtain amenorrhea. The progestrone-only minipill causes significant irregular spotting, so if full suppression is the goal, then other progestins can be used daily, such as norethindrone 2.5 or 5 mg or micronized progestrone 200 mg.

Progesterone Intrauterine Device
The 5 yr levonorgestrel-intrauterine device has now been used for many teenagers for contraception as well as heavy menses. Teens with special needs might require anesthesia for insertion if the exam is very difficult because of discomfort, contractures, or a narrow vagina. Checking for strings in a clinic setting may be challenging; however, the intrauterine device location can be confirmed by sonography. There may be a significant amount of irregular bleeding and spotting in the 1st several mo, but there is 20% amenorrhea after insertion and up to 50% amenorrhea after 1 year of use. The bleeding profile of the newer and smaller 3 year progesterone intrauterine device may not be as helpful for menstrual suppression as the amenorrhea rates from the initial studies by the manufacturer are 6% at 1 year, but more studies are needed.

Implants
Progestin subdermal implants have relatively low amenorrhea rates and high rates of unscheduled bleeding and therefore might not be ideal for teens with special needs, as they also require significant patient cooperation for insertion.

Hormones and Antiepileptic Drugs
Certain enzyme-inducing seizure medications can interfere with oral contraceptives, change their effectiveness, and/or lead to intermittent bleeding. Higher estrogen dose or shorter injection intervals for DMPA may be considered. The only antiepileptic medication that is affected by combined oral contraceptives is lamotrigine; consequently, the dose of that medication may need to be adjusted if used in conjunction with hormones.

Surgical Methods
Surgical procedures such as endometrial ablation, a procedure where the lining of the uterus is surgically removed, and hysterectomy are available for treatment of abnormal periods in adults, but they should only rarely be used in extreme situations for teenagers where all other methods have failed and the patient’s health is severely compromised by her cycles. Endometrial ablation only leads to amenorrhea approximately 30% of the time and has a higher failure rate in women younger than 40 yr of age. Ethical considerations around these methods leading to infertility and consent issues are complicated, and state law varies on this topic.

CONTRACEPTION
See also Chapter 117.

The menstrual manipulation methods discussed above can also be used for contraception and if a request for birth control is made, an evaluation of the patient's ability to consent to sexual activity and the safety of her environment should be done. The method chosen should be the safest method for her situation with the highest protection rate. If she is dependent on others a long-acting reversible contraceptive method may be advisable. Sexually transmitted infections and condom use should be addressed with the teen and specific guidelines on how to obtain condoms and negotiate its use may be needed. A discussion about postcoital contraception is recommended, as well as ways to help the teen obtain this if indicated.

555.1 Female Genital Mutilation/Cutting
Robert M. Kliegman

Female genital mutilation/cutting (FGM/C) is a common practice in many parts of the world and is considered a form of child abuse and is illegal in most countries. It is estimated that more than 125 million women in 29 countries have undergone FGM/C (Fig. 555.1). FGM/C breaches international human rights laws and is considered a criminal act.

FGM/C has no health benefit. It threatens the health of girls and women having adverse effects on their psychologic, sexual, and reproductive well-being (Table 555-1). In addition, it increases the risk of HIV infection.

CLASSIFICATIONS
Type I: Partial or complete removal of the clitoris, prepuce, or both
Type II: Mutilation or cutting producing partial or complete removal of the clitoris and labia minora with or without excision of the labia majora
Type III: Infibulation; narrowing and sealing of the vaginal orifice by cutting and apposition of the labia minora or majora with or without excision of the clitoris
Type IV: All other harmful procedures
Bibliography

West African women are at greater risk of type II FGM/C, while those in northeast and east Africa and the Middle East are subjected to type III FGM/C. Nonetheless because of migration, women and girls in the United States and Western Europe may undergo FGM/C by traditional practitioners or, rarely, ethnic minority obstetricians or other physicians. Many ethnic women at risk for FGM/C living in the United States or Western Europe are more ambivalent about the procedure demonstrating a conflict between 2 cultures.

**MANAGEMENT**

This is a complex ethnic minority issue that often goes undetected until complications develop, either acutely from the procedure or during pregnancy. Criminalization alone will not eliminate this practice because it is performed in secret, and women are reluctant to discuss this with their healthcare provider, but laws against these procedures are an important step in reducing the number of women subjected to FGM/C.

Surgical repair, such as clitoral reconstruction with removal of scar tissue has been quite beneficial in decreasing pain and enhancing pleasure, including orgasm. Furthermore, women report a positive effect on their self-image and female identity as well as a new sense of “completeness” after reconstructive surgery.

Bibliography

The pituitary gland is the major regulator of an elaborate hormonal system. The pituitary gland receives signals from the hypothalamus and responds by sending pituitary hormones to target glands. The target glands produce hormones that provide negative feedback at the level of the hypothalamus and pituitary (Fig. 556-1). This feedback mechanism enables the pituitary to regulate the amount of hormone released into the bloodstream by the target glands. The pituitary's central role in this hormonal system and its ability to interpret and respond to a variety of signals have led to its designation as the "master gland." Table 556-1 lists hypothalamic and pituitary hormones and their functions.

ANATOMY
The pituitary gland is located at the base of the skull in a saddle-shaped cavity of the sphenoid bone called the sella turcica. The bony structure protects and surrounds the pituitary bilaterally and inferiorly. The dura, a dense layer of connective tissue, forms the roof of the sella. An external layer of the dura continues into the sella to form its lining. As a result, the pituitary is extradural and is not normally in contact with cerebrospinal fluid. The pituitary gland is connected to the hypothalamus by the pituitary stalk. The pituitary gland is composed of an anterior (adenohypophysis) and a posterior (neurohypophysis) lobe. The anterior lobe constitutes approximately 80% of the gland.

EMBRYOLOGY
The anterior pituitary gland originates from the Rathke pouch as an invagination of the oral ectoderm. It then detaches from the oral epithelium and becomes an individual structure of rapidly proliferating cells. By 6 wk of gestation, the connection between the Rathke pouch and the oropharynx is completely obliterated, and the pouch establishes a direct connection with the downward extension of the hypothalamus, which gives rise to the pituitary stalk. Persistent remnants of the original connection between the Rathke pouch and the oral cavity can develop into craniopharyngiomas (see Chapter 497), the most common type of tumor in this area.

VASCULAR SUPPLY
The arterial blood supply of the pituitary gland originates from the internal carotid via the inferior, middle, and superior hypophyseal arteries. This network of vessels forms a unique portal circulation connecting the hypothalamus and pituitary. The branches of the superior hypophyseal arteries penetrate the stalk and form a network of vessels that traverse the pituitary stalk and terminate in a network of capillaries within the anterior lobe. It is through this portal venous system that hypothalamic hormones are delivered to the anterior pituitary gland. Anterior pituitary hormones, in turn, are secreted into a secondary plexus of portal veins that drain into the dural venous sinuses.

ANTERIOR PITUITARY CELL TYPES
A series of sequentially expressed transcriptional activation factors directs the differentiation and proliferation of anterior pituitary cell types. These proteins are members of a large family of DNA-binding proteins resembling homeobox genes. The consequences of mutations in several of these genes are evident in human forms of multiple pituitary hormone deficiency. Five cell types in the anterior pituitary produce 6 peptide hormones. Somatotropes produce growth hormone (GH), lactotropes produce prolactin (PRL), thyrotropes make thyroid-stimulating hormone (TSH), corticotropes express proopiomelanocortin, the precursor of adrenocorticotropic hormone (ACTH), and gonadotropes express luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Growth Hormone
Human GH is a 191-amino-acid single-chain polypeptide that is synthesized, stored, and secreted by somatotropes in the pituitary. Its gene (GH1) is the first in a cluster of 5 closely related genes on the long arm of chromosome 17 (q22-24). The 4 other genes (CS1, CS2, GH2, and CSP) have >90% sequence identity with the GH1 gene. GH is secreted in a pulsatile fashion under the regulation of hypothalamic hormones. The alternating secretion of growth hormone–releasing hormone, which stimulates GH release, and somatostatin, which inhibits GH release, accounts for the rhythmic secretion of GH. Peaks of GH occur when peaks of growth hormone–releasing hormone coincide with troughs of somatostatin. Ghrelin, a peptide produced in the arcuate nucleus of the hypothalamus and in much greater quantities by the stomach, also stimulates GH secretion. In addition to the 3 hypothalamic hormones, physiologic factors play a role in stimulating and inhibiting GH. Sleep, exercise, physical stress, trauma, acute illness, puberty, fasting, and hypoglycemia stimulate the release of GH whereas hyperglycemia, hypothryoidism, and glucocorticoids inhibit GH release.

GH binds to receptor molecules on the surface of target cells. The GH receptor is a 620-amino-acid, single-chain molecule with an extracellular domain, a single membrane-spanning domain, and a cytoplasmic domain. Proteolytically cleaved fragments of the extracellular domain circulate in plasma and act as a GH-binding protein. As in other members of the cytokine receptor family, the cytoplasmic domain of the GH receptor lacks intrinsic kinase activity; instead, GH binding induces receptor dimerization and activation of a receptor-associated Janus kinase (Jak2). Phosphorylation of the kinase and other protein substrates initiates a series of events that leads to alterations in nuclear gene transcription. The signal transducer and activator of transcription 5b (STAT5b) plays a critical role in linking receptor activation to changes in gene transcription.

The biologic effects of GH include increases in linear growth, bone thickness, soft tissue growth, protein synthesis, fatty acid release from adipose tissue, insulin resistance, and blood glucose. The mitogenic actions of GH are mediated through increases in the synthesis of insulin-like growth factor 1 (IGF-1), formerly named somatomedin C, a 70-amino-acid single-chain peptide coded for by a gene on the long arm of chromosome 12. IGF-1 has considerable homology to
insulin. Circulating IGF-1 is synthesized primarily in the liver and formed locally in mesodermal and ectodermal cells, particularly in the growth plates of children, where its effect is exerted by paracrine or autocrine mechanisms. Circulating levels of IGF-1 are related to blood levels of GH and to nutritional status. IGF-1 circulates bound to several different binding proteins. The major one is a 150-kDa complex (IGFBP3) that is decreased in GH-deficient children. Human recombinant IGF-1 might have therapeutic potential in conditions characterized by end organ resistance to GH such as Laron syndrome and the development of antibodies to administered GH. IGF-1 is a 67-amino-acid single-chain protein that is coded for by a gene on the short arm of chromosome 11. It has homology to IGF-1. Less is known about its physiologic role, but it appears to be an important mitogen in bone cells, where it occurs in a concentration many times higher than that of IGF-1.

**Prolactin**

PRL is a 199-amino-acid peptide made in pituitary lactotropes. The regulation of PRL is unique because PRL is consistently secreted unless it is actively inhibited by dopamine, a peptide produced by neurons in the hypothalamus. Disruption of the hypothalamus or pituitary stalk can result in elevated PRL levels. Dopamine antagonists, states of primary hypothyroidism, administration of thyrotropin-releasing hormone (TRH), and pituitary tumors result in increased serum levels of PRL. Dopamine agonists and processes causing destruction of the pituitary cause reduced levels of PRL.

The primary physiologic role for PRL is the initiation and maintenance of lactation. PRL prepares the breasts for lactation and stimulates milk production postpartum. During pregnancy, PRL stimulates the development of the milk-secretory apparatus, but lactation does not occur because of the high levels of estrogen and progesterone. After delivery, the estrogen and progesterone levels drop and physiologic stimuli such as suckling and nipple stimulation signal PRL release and initiate lactation.

**Thyroid-Stimulating Hormone**

TSH consists of 2 glycoprotein chains (α, β) linked by hydrogen bonding; the α-subunit, which is composed of 89 amino acids and is identical to other glycoproteins (FSH, LH, and human chorionic gonadotropin), and the β-subunit, composed of 112 amino acids, that is specific for TSH.

TSH is stored in secretory granules and released into circulation primarily in response to TRH, which is produced by the hypothalamus. TRH is released from the hypothalamus into the hypothalamic–pituitary portal system and ultimately stimulates TSH release from pituitary thyrotropes. TSH stimulates release of thyroxine (T₄) and triiodothyronine (T₃) from the thyroid gland through the formation of cyclic adenosine monophosphate and the G protein second messenger system. In addition to the negative feedback inhibition by T₃, the release of TRH and TSH is inhibited by dopamine, somatostatin, and glucocorticoids.

Deficiency of TSH results in inactivity and atrophy of the thyroid gland, whereas excess TSH results in hypertrophy and hyperplasia of the thyroid gland.

**Adrenocorticotropic Hormone**

ACTH is a 39-amino-acid single-chain peptide that is derived by proteolytic cleavage from proopiomelanocortin, a 240-amino-acid
V1 receptors in smooth muscle cells and hepatocytes and exerts pressor to water. V2 receptors also mediate the von Willebrand factor and proteins to increase adenylyl cyclase activity and increase permeability vasopressin 2 receptors in the collecting duct, which act through Glates translocation of water channels through its interaction with ing the permeability of the renal collecting duct to water. Antidiuretic Hormone

Adrenocorticotropic hormone (ACTH). Secretion of ACTH is regulated by corticotropin-releasing hormone (CRH), a 41-amino-acid peptide found predominantly in the median eminence but also in other areas in and outside of the brain. ACTH is secreted in a diurnal pattern. It acts on the adrenal cortex to stimulate cortisol synthesis and secretion. ACTH and cortisol levels are highest in the morning at the time of waking, are low in the late afternoon and evening, and reach their nadir 1-2 hr after beginning sleep. ACTH also appears to be the principalpigmentary hormone in humans. Similar to TRH and TSH, CRH and ACTH function through the formation of cyclic adenosine monophosphate and the G protein second-messenger system. Although CRH is the primary regulator of ACTH secretion, other hormones play a role. Arginine vasopressin, oxytocin, angiotensin II, and cholecystokinin stimulate release of CRH and ACTH, whereas atrial natriuretic peptide and opioids inhibit release of CRH and ACTH. Similar to the feedback inhibition T3, on TRH and TSH, cortisol also inhibits CRH and ACTH. Physiologic conditions, such as stress, fasting, and hypoglycemia, also stimulate release of CRH and ACTH.

ACTH and cortisol levels are highest in the morning at the time of waking, are low in the late afternoon and evening, and reach their nadir 1-2 hr after beginning sleep. ACTH also appears to be the principal pigmen

ADH and its accompanying protein neurophysin II are encoded by the same gene. A single preprohormone is cleaved and the 2 are transported to neurosecretory vesicles in the posterior pituitary. The 2 are released in equimolar amounts.

ADH has a short half-life and responds quickly to changes in hydration. The stimuli for its release are increased plasma osmolality, perceived by osmoreceptors in the hypothalamus, and decreased blood volume, perceived by baroreceptors in the carotid sinus of the aortic arch.

**Oxytocin**

Oxytocin stimulates uterine contractions at the time of labor and delivery in response to distention of the reproductive tract and stimulates smooth muscle contraction in the breast during suckling, which results in milk letdown. Studies suggest that oxytocin also plays a role in orgasm, social recognition, pair bonding, anxiety, trust, love, and maternal behavior. Most recently, through the interaction with its G-protein-coupled receptor in pancreatic and adipose tissue, oxytocin appears to play a significant role in appetite regulation and obesity by inducing anorexia.

Bibliography
Hypopituitarism denotes underproduction of growth hormone (GH) alone or in combination with deficiencies of other pituitary hormones. Affected children have postnatal growth impairment that is specifically corrected by replacement of GH. The incidence of congenital hypopituitarism is thought to be between 1 in 4,000 and 1 in 10,000 live births. With expanding knowledge of the genes that direct pituitary development or hormone production, an increasing proportion of cases can be attributed to specific genetic disorders. Mutations in 7 candidate genes account for 13% of isolated growth hormone deficiency (IGHD) and 20% of multiple pituitary hormone deficiency (MPHD) cases. The likelihood of finding mutations is increased by consanguinity and occurrence in siblings or across generations. The genes, hormonal phenotypes, associated abnormalities, and modes of transmission for such established genetic disorders are shown in Tables 557-1 through 557-4. Acquired hypopituitarism usually has a later onset and different causes (Table 557-5).

**MULTIPLE PITUITARY HORMONE DEFICIENCY**

**Genetic Forms**

Sequentially expressed transcriptional activation factors direct the differentiation and proliferation of anterior pituitary cell types. These proteins are members of a large family of DNA-binding proteins resembling homeobox genes. Mutations produce different forms of MPHD. *PROPl* and *POU1F1* genes are expressed fairly late in pituitary development only in cells of the anterior pituitary and result in hypopituitarism without anomalies of other organ systems. The *HESX1, LHX3, LHX4*, and *PTX2* genes are expressed at earlier stages and are not restricted to the pituitary. Mutations in these genes tend to produce phenotypes that extend beyond hypopituitarism to include abnormalities in other organs.

PROP1

PROP1 is found in the nuclei of somatotropes, lactotropes, and thyrotropes. Its roles include turning on POU1F1 expression, hence its name prophet of PIT1. Mutations of PROP1 are the most common explanation for recessive MPHD and are 10 times as common as the combined total of mutations in other pituitary transcription factor genes. Deletions of 1 or 2 base pairs in exon 2 are most common, followed by missense, nonsense, and splice-site mutations. Anterior pituitary hormone deficiencies are seldom evident in the neonatal period. The median age at diagnosis of GH deficiency is around 6 yr. Recognition of thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone, and adrenocorticotropic (ACTH) deficiencies is delayed relative to recognition of GH deficiency. Anterior pituitary size is small in most patients, but in others there is progressive enlargement of the pituitary.

POU1F1 (PIT1)

POU1F1 (formerly PIT1) was identified as a nuclear protein that binds to the GH and prolactin promoters. It is necessary for emergence and mature function of somatotropes, lactotropes, and thyrotropes. Dominant and recessive mutations in POU1F1 are responsible for

Heterozygous mutations

Table 557-4  Proposed Classification of Growth Hormone Insensitivity

Primary GH insensitivity (hereditary defects)
- GH receptor defect (may be positive or negative for GH-binding protein)
  - Extracellular mutation (e.g., Laron syndrome)
  - Cytoplasmic mutation
  - Intracellular mutation
- GH signal transduction defects (distal to cytoplasmic domain of GH receptor)
  - Stat5b mutations
  - Insulin-like growth factor-1 defects
    - IGF-1 gene deletion
    - IGF-1 transport defect (ALS mutation)
    - IGF-1 receptor defect
- Bioactive GH molecule (responds to exogenous GH)

Secondary GH insensitivity (acquired defects)
- Circulating antibodies to GH that inhibit GH action
- Antibodies to the GH receptor
- GH insensitivity caused by malnutrition, liver disease, catabolic states, diabetes mellitus
- Other conditions that cause GH insensitivity

GH insensitivity: Clinical and biochemical features of IGF-1 deficiency and insensitivity to exogenous GH, associated with GH secretion that would not be considered abnormally low.

GH insensitivity syndrome: GH insensitivity associated with the recognizable dysmorphic features described by Laron.

Partial GH insensitivity: GH insensitivity in the absence of dysmorphic features described by Laron.

ALS, acid labile subunit; GH, growth hormone; IGF, insulin-like growth factor.

Complete deficiencies of GH and prolactin and variable TSH deficiency. Affected patients exhibit nearly normal fetal growth but experience severe growth failure in the 1st yr of life. With normal production of LH and follicle-stimulating hormone, puberty develops spontaneously, though at a later than normal age. These patients are not at risk for development of ACTH deficiency. Anterior pituitary size is normal to small.

HESX1
The HESX1 gene is expressed in precursors of all 5 cell types of the anterior pituitary early in embryologic development. Mutations result in a complex phenotype with defects in development of the optic nerve. Heterozygotes for loss-of-function mutations show the combinations of isolated GH deficiency and optic nerve hypoplasia. Homozygotes can have full expression of septooptic dysplasia. This condition combines incomplete development of the septum pellucidum with optic nerve hypoplasia and other midline abnormalities. Clinical observation of nystagmus and visual impairment in infancy leads to the discovery of optic nerve and brain abnormalities. Septooptic dysplasia is associated with anterior and/or posterior pituitary hormone deficiencies in approximately 25% of the cases. These patients often show the triad of a small anterior pituitary gland, an attenuated pituitary stalk, and an ectopic posterior pituitary bright spot. The great majority of patients with septooptic dysplasia do not have HESX1 mutations. The etiology might involve mutations in another gene or a nongenetic explanation (see Chapters 591 and 631).

LHX3 and LHX4
The phenotype produced by recessive loss-of-function mutations of the LHX3 gene resembles that produced by PROP1 mutations. There are
deficiencies of GH, prolactin, TSH, LH, and follicle-stimulating hormone, but not ACTH. Some affected persons show enlargement of the anterior pituitary. The first patients to be described had the unusual findings of a short neck and a rigid cervical spine. They were only able to rotate their necks approximately 90 degrees compared with the normal rotation of 150-180 degrees. Dominantly inherited mutations in the structurally similar LHX4 gene consistently produce GH deficiency, with the variable presence of TSH and ACTH deficiencies. Additional findings can include a very small V-shaped pituitary fossa, Chiari I malformation, and an ectopic posterior pituitary.

Other Congenital Forms

Pituitary hypoplasia can occur as an isolated phenomenon or in association with more extensive developmental abnormalities such as anencephaly or holoprosencephaly. Midfacial anomalies (cleft lip, palate; see Chapter 310) or the finding of a solitary maxillary central incisor indicates a high likelihood of GH or other anterior or posterior hormone deficiencies. At least 12 genes have been implicated in the complex genetic etiology of holoprosencephaly (see Chapter 591.7). The anterior pituitary is small, in keeping with the observation that somatotropes during pituitary development and disrupt the most important signals for release of GH. The anterior pituitary is small, in keeping with the observation that somatotropes normally account for >50% of pituitary volume. There is some compromise of fetal growth followed by severe compromise of postnatal growth.

GH1

The GH1 gene is one of a cluster of 5 genes on chromosome 17q22-24. This cluster arose through successive duplications of an ancestral GH gene. Unequal crossing over at meiosis has produced a variety of gene deletions. Small deletions (<10 kb) remove only the GH1 gene, whereas large deletions (45 kb) remove 1 or more of the adjacent genes (CSL, CS1, GH2, and CS2). The growth phenotype is identical with deletion of GH1 alone or GH1 together with 1 or more of the adjacent genes. Loss of the CSL, GH2, and CS2 genes without loss of GH1 causes deficiency of choricon somatomammotropin and placental GH in the maternal circulation, but it does not result in fetal or postnatal growth retardation. Most children with GH1 gene deletions respond very well to recombinant GH treatment, but some develop antibodies to GH and cease growing.

Recessively transmitted mutations in the GH1 gene produce a similar phenotype. Missense, nonsense, and frameshift mutations have been described. Autosomal dominant IGHD is also caused by mutations in GH1. The mutations usually involve splice-site errors in intron 3 and result in a variant protein that lacks the amino acids normally encoded by exon 3. Accumulation of this protein interferes with the processing, storage, and secretion of the normal GH protein and may result in additional deficiencies of TSH and/or ACTH. There are several reports of mutations in GH1 that lead to variant proteins with reduced biological activity.

X-Linked Isolated Growth Hormone Deficiency

Two loci on the X chromosome have been associated with hypopituitarism. The first lies at Xq21.3-q22 in the region of the Bruton thymidine kinase (BTK) gene. Mutations in this region produce hypogammaglobulinemia as well as IGHD. The second locus maps farther out on the long arm, at Xq24-q27.1, a region containing the SOX2 transcription factor gene. Abnormalities in this locus have been linked to IGHD with intellectual disability as well as to MPHHD with the triad of pituitary hypoplasia, missing pituitary stalk, and ectopic posterior pituitary gland.
Acquired Forms

The GH axis is more susceptible to disruption by acquired conditions than are other hypothalamic-pituitary axes. Recognized causes of acquired GH deficiency include the use of radiotherapy for malignancy, meningitis, histiocytosis, and trauma.

Children who receive radiotherapy for central nervous system tumors or prevention of central nervous system malignancies (e.g., leukemia) are at risk for developing GH deficiency. Spinal irradiation contributes to disproportionately poor growth of the trunk. Growth typically slows during radiation therapy (see Chapter 718) or chemotherapy (see Chapter 494), improves for 1-2 yr, and then declines with the development of GH deficiency. The dose and frequency of radiotherapy are important determinants of hypopituitarism. GH deficiency is almost universal 5 yr after therapy with a total dose ≥35 Gy. More subtle defects are seen with doses around 20 Gy. Deficiency of GH is the most common defect, but deficiencies of TSH and ACTH can also occur. In contrast to other forms of hypopituitarism, puberty tends to be early rather than delayed (see Chapter 562.3). The clinician is likely to encounter children in the 8-10 yr age range who are growing at rates that are normal for chronological age but subnormal for stage of pubertal development.

GROWTH HORMONE INSENSITIVITY

Abnormalities of the Growth Hormone Receptor

GH insensitivity is caused by disruption of pathways distal to production of GH. Laron syndrome involves mutations of the GH receptor. Children with this condition clinically resemble those with severe IGHD. Birth length tends to be about 1 SD below the mean, and severe short stature with lengths >4 SD below the mean is present by 1 yr of age. Resting and stimulated GH levels tend to be high and insulin-like growth factor (IGF) 1 levels are low. The GH receptor has an extracellular GH-binding domain, a transmembrane domain, and an intracellular signaling domain. Mutations in the extracellular domain interfere with binding of GH. Serum GH-binding protein activity, representing the circulating form of the membrane receptor for GH, is generally low. Mutations in the transmembrane domain can interfere with anchoring of the receptor to the plasma membrane. In these cases, circulating GH-binding protein activity is normal or high. Mutations in the intracellular domain interfere with JAK/STAT signaling.

Postreceptor Forms of Growth Hormone Insensitivity

Some children with severe growth failure, high GH and low IGF-1 levels, and normal GH-binding protein levels have abnormalities distal to the GH binding and activation of the GH receptor. Several have been found to have mutations in the gene encoding signal transducer and activator of transcription 5b (STAT5b). Disruption of this key intermediate connecting receptor activation to gene transcription produces growth failure similar to that seen in Laron syndrome. These patients also suffer from chronic pulmonary infections, consistent with important roles for STAT5b in interleukin cytokine signaling.

IGF-1 Gene Abnormalities

Abnormalities of the IGF-1 gene produce severe prenatal and postnatal growth impairment. Microcephaly, intellectual disability, and deafness are present in patients with exon deletion and a missense mutation. These patients can be expected to respond to recombinant IGF-1 treatment.

Insulin-Like Growth Factor–Binding Protein Abnormalities

Mutation of the gene encoding the acid labile subunit of the circulating 165-kDa IGF-1, IGF-BP3, acid labile subunit complex has been associated with short stature. Total IGF-1 levels were very low. The index case, with homozygosity for an acid labile subunit mutation, did not show an increase in IGF-1 levels or an increase in growth rate during GH treatment.

IGF-1 Receptor Gene Abnormalities

Mutations of the IGF-1 receptor also compromise prenatal and postnatal growth. The phenotype does not appear to be as severe as that seen with absence of IGF-1. Adult heights are closer to the normal range, and affected patients do not have intellectual disability or deafness.

CLINICAL MANIFESTATIONS

Congenital Hypopituitarism

The child with hypopituitarism is usually of normal size and weight at birth, although those with MPHD and genetic defects of the GH1 or GHR gene have birth lengths that average 1 SD below the mean. Children with severe defects in GH production or action typically fall more than 4 SD below the mean for length by 1 yr of age. Those with less-severe deficiencies grow at rates below the 25th percentile for age and gradually diverge from normal height percentiles. Delayed closure of the epiphyses permits growth beyond the normal age when growth should be complete. Features of GH insensitivity are noted in Table 557-6.

Infants with congenital defects of the pituitary or hypothalamus may present with neonatal emergencies such as apnea, cyanosis, or severe hypoglycemia with or without seizures. Prolonged neonatal jaundice is common. It involves elevation of conjugated and unconjugated bilirubin and may be mistaken for neonatal hepatitis. Nystagmus can suggest septooptic dysplasia (see Chapter 591). Micropenis in boys provides an additional diagnostic clue. Deficiency of GH may be accompanied by hypothalamic dysfunction (see Chapter 575) and hypothyroidism (see Chapter 565) as well as gonadotropin deficiency (see Chapters 583.2 and 586.2).

On physical examination, the head is round and the face is short and broad. The frontal bone is prominent, and the bridge of the nose is depressed and saddle shaped. The nose is small, and the nasolabial folds are well developed. The eyes are somewhat bulging. The mandible and the chin are underdeveloped, and the teeth, which erupt late, are often crowded. The neck is short and the larynx is small. The voice is high-pitched and remains high after puberty. The extremities are well proportioned, with small hands and feet. Weight for height is usually

normal, but an excess of body fat and a deficiency of muscle mass contribute to a pugy appearance. The genitals are usually small for age, and sexual maturation may be delayed or absent. Facial, axillary, and pubic hair usually is lacking, and the scalp hair is fine. Intelligence is usually normal for age and the children may seem precocious compared to children of a similar size.

**Acquired Hypopituitarism**
The child is normal initially, and manifestations similar to those seen in idiopathic pituitary growth failure gradually appear and progress. When complete or almost complete destruction of the pituitary gland occurs, signs of pituitary insufficiency are present. Atrophy of the adrenal cortex, thyroid, and gonads results in loss of weight, asthenia, sensitivity to cold, mental torpor, and absence of sweating. Sexual maturation fails to take place or regresses if already present. There may be atrophy of the gonads and genital tract with amenorrhea and loss of pubic and axillary hair. There is a tendency to hypoglycemia. Growth slows dramatically. Diabetes insipidus (see Chapter 497) and central adrenal insufficiency may first appear after surgical intervention. In children with craniopharyngiomas, visual field defects, optic atrophy, and symptoms, especially with craniopharyngiomas. Evidence of pituitary insufficiency may first appear after surgical intervention. In children with craniopharyngiomas, visual field defects, optic atrophy, papilledema, and cranial nerve palsy are common.

**LABORATORY FINDINGS**
GH deficiency should be suspected in children with severe postnatal growth failure (Table 557-7). Criteria for growth failure include height below the 1st percentile for age and sex or height >2 SD below sex-adjusted mid-parent height. Acquired GH deficiency can occur at any age, and when it is of acute onset, height may be within the normal range. A strong clinical suspicion is important in establishing the diagnosis because laboratory measures of GH sufficiency lack specificity. Observation of low serum levels of IGF-1 and the GH-dependent IGF-BP3 can be helpful, but IGF-1 and IGF-BP3 levels should be matched to normal values for skeletal age rather than chronological age. Values in the upper part of the normal range for age effectively exclude GH deficiency. IGF-1 values in normally growing children and those with hypopituitarism overlap during infancy and early childhood.

Definitive diagnosis of GH deficiency traditionally requires demonstration of absent or low levels of GH in response to stimulation. A variety of provocative tests have been devised that rapidly increase the level of GH in normal children. These include administration of insulin, arginine, clonidine, or glucagon. In chronic GH deficiency, the demonstration of subnormal linear growth, a delayed skeletal age, and low peak levels of GH (<10 ng/mL) in each of 2 provocative tests are compatible with GH deficiency. In acute GH deficiency, a high clinical suspicion of GH deficiency and low peak levels of GH (<10 ng/mL) in each of 2 provocative tests are compatible with GH deficiency. This rather arbitrary cutoff point is higher than the 3 or 5 ng/mL criteria used for diagnosis of adult GH deficiency. There is no consensus regarding adoption of criteria that take into account age, sex, and GH assay characteristics. Some studies indicate that a majority of normal prepubertal children fail to achieve GH values >10 ng/mL with 2 pharmacologic tests. The researchers suggest that 3 days of estrogen priming should be used before GH testing to achieve greater diagnostic specificity.

In addition to establishing the diagnosis of GH deficiency, it is necessary to examine other pituitary functions. Levels of TSH, free thyroxine, ACTH, cortisol, gonadotropins, and gonadal steroids might provide evidence of other pituitary hormonal deficiencies. Antidiuretic hormone deficiency may be established by appropriate studies.

**RADIOLOGIC FINDINGS**
Conventional x-ray films of the skull have been replaced by CT and MRI. CT is appropriate for recognizing suprasellar calcification associated with craniopharyngiomas and bony changes accompanying histiocytosis. MRI provides a much more detailed view of hypothalamic and pituitary anatomy. Many cases of severe early-onset MPHDS show the triad of a small anterior pituitary gland, a missing or attenuated pituitary stalk, and an ectopic posterior pituitary bright spot at the base of the hypothalamus. Subnormal anterior pituitary height, implying a small anterior pituitary, is common in genetic and idiopathic causes of IGHD. Craniopharyngiomas are common and pituitary adenomas are rare in children with hypopituitarism. Both hypoplastic and markedly enlarged anterior pituitary glands are seen in patients with PROP1 or LHX3 mutations.

Skeletal maturation is delayed in patients with IGHD and may be even more delayed when there is combined GH and TSH deficiency. Dual-photon x-ray absorptiometry shows deficient bone mineralization, deficiencies in lean body mass, and a corresponding increase in adiposity.

**DIFFERENTIAL DIAGNOSIS**
The causes of growth disorders are legion. Systemic conditions, such as inflammatory bowel disease, celiac disease, occult renal disease, and anemia, must be considered. Patients with systemic conditions often have greater loss of weight than length. A few otherwise normal children are short (i.e., >3 SD below the mean for age) and grow 5 cm/yr or less but have normal levels of GH in response to provocative tests and normal spontaneous episodic secretion. Most of these children show increased rates of growth when treated with GH in doses comparable to those used to treat children with hypopituitarism. Plasma levels of IGF-1 in these patients may be normal or low. Several groups of treated children have achieved final or near-final adult heights. Different studies have found changes in adult height that range from −2.5 to +7.5 cm compared with pretreatment predictions. There are no methods that can reliably predict which of these children will become

### Table 557-7: Evaluation of Suspected Growth Hormone Deficiency

| Growth-related history and patient physical exam | • Infants and children with GHD have growth failure  
• Short stature and growth failure may be the only clinical features present  
• GHD affects ~1 in 3,500 children |
|-------------------------------|---------------------------------|
| Imaging and other evaluations | • Diagnosis is based on clinical, auxologic, and biochemical parameters  
• Radiologic evaluation of bone age  
• Central nervous system MRI or CT scan to evaluate the hypothalamic-pituitary region and to exclude other conditions  
• Evaluation and management by a pediatric endocrinologist |
| Laboratory evaluation | • Measurements of GH, IGF-1, and IGF-1–binding protein levels  
• Determination of peak GH levels after stimulation test |
| Special testing (if applicable) | • Family history and genetic analyses (e.g., search for PROP1 and POU1F1 mutations) |
| Rationale for treatment and treatment modalities | • Replacement therapy with rhGH (GHT)  
• Predictors of greater benefit with GHT in GHD include early initiation of treatment, higher rhGH dose, and IGF-1–guided dosing  
• GHT should be started as soon as GHD is diagnosed |

**GH**, growth hormone; **GHD**, growth hormone deficiency; **GHT**, growth hormone therapy; **IGF**, insulin-like growth factor; **POU1F1**, POU class 1 homeobox box 1; **PROP1**, homeobox protein prophet of Pit1; **rhGH**, human recombinant growth hormone.

taller in adulthood as a result of GH treatment and which will have compromised adult height.

Diagnostic strategies for distinguishing between permanent GH deficiency and other causes of impaired growth are imperfect. Children with a combination of genetic short stature and constitutional delay of growth have short stature, below-average growth rates, and delayed bone ages. Many of these children exhibit minimal GH secretory responses to provocative stimuli. When children in whom idiopathic or acquired GH deficiency is diagnosed are treated with human GH (hGH) and retested as adults, the majority have peak GH levels within the normal range.

Constitutional Growth Delay

Constitutional growth delay is one of the variants of normal growth commonly encountered by the pediatrician. Length and weight measurements of affected children are normal at birth, and growth is normal for the 1st 4-12 mo of life. Height is sustained at a lower percentile during childhood. The pubertal growth spurt is delayed, so their growth rates continue to decline after their classmates have begun to accelerate. Detailed questioning often reveals other family members (often 1 or both parents) with histories of short stature in childhood, delayed puberty, and eventual normal stature. IGF-1 levels tend to be low for chronological age but within the normal range for bone age. GH responses to provocative testing tend to be lower than in children with a more typical timing of puberty. The prognosis for these children to achieve normal adult height is guarded. Predictions based on height and bone age tend to overestimate eventual height to a greater extent in boys than in girls. Boys with >2 yr of pubertal delay can benefit from a short course of testosterone therapy to hasten puberty after 14 yr of age. The cause of this variant of normal growth is thought to be persistence of the relatively hypogonadotropic state of childhood (see Chapter 15).

Primary Hypothyroidism

Primary hypothyroidism (see Chapter 565) is more common than GH deficiency. Low total or free thyroxine and elevated TSH levels establish the diagnosis. Responses to GH provocative tests may be subnormal and the sella may be enlarged. Pituitary hyperplasia recedes during treatment with thyroid hormone. Because thyroid hormone is a necessary prerequisite for normal GH synthesis, it must always be assessed before GH evaluation.

Psychosocial Causes

Emotional deprivation is an important cause of retardation of growth and mimics hypopituitarism. The condition is known as psychosocial dwarfism, material deprivation dwarfism, or hyperphagie short stature. The mechanisms by which sensory and emotional deprivation interfere with growth are not fully understood. Functional hypopituitarism is indicated by low levels of IGF-1 and by inadequate responses of GH to provocative stimuli. Puberty may be normal or even premature. Appropriate history and careful observations reveal disturbed mother-child or family relations and provide clues to the diagnosis (see Chapter 40). Proof may be difficult to establish because the parents or caregivers often hide the true family situation from professionals, and the children rarely divulge their plight. Emotionally deprived children often have perverted or voracious appetites, enuresis, encopresis, insomnia, crying spasms, and sudden tantrums. The subgroup of children with hyperphagia and a normal body mass index tends to show catch-up growth when placed in a less stressful environment.

TREATMENT

Recombinant hGH has been available by prescription since 1982. There are currently 8 brands marketed in the United States. They are therapeutically equivalent, with the major differences consisting of proprietary devices for subcutaneous injection and availability of solubilized liquid forms or powders needing reconstitution before injection. At present none of the products are available in long-acting repository forms.

The FDA has approved 8 indications for GH treatment to promote growth. They are GH deficiency, Turner syndrome, chronic renal failure before transplantation, idiopathic short stature, small-for-gestational age short stature, Prader-Willi syndrome, SHOX gene abnormality, and Noonan syndrome. FDA approval for a given indication does not ensure that a patient’s third-party insurance carrier will approve payment for the drug. The Pediatric Endocrine Society, the Academy of Pediatrics, and the GH Research Society have published guidelines for hGH treatment of children with classic GH deficiency. Treatment should be started as soon as possible to narrow the gap in height between patients and their classmates during childhood and to have the greatest effect on mature height. The recommended dose of hGH is 0.18-0.3 mg/kg/wk during childhood. Higher doses have been used during puberty. Recombinant GH is administered subcutaneously in 6 or 7 divided doses. Maximal response to GH occurs in the 1st yr of treatment. Growth velocity during this 1st yr is typically above the 95th percentile for age. With each successive yr of treatment, the growth rate tends to decrease. If growth rate drops below the 25th percentile, compliance should be evaluated before the dose is increased.

Concurrent treatment with GH and a gonadotropin-releasing hormone agonist has been used in the hope that interruption of puberty will delay epiphyseal fusion and prolong growth. This strategy can increase adult height. It can also increase the discrepancy in physical maturity between GH-deficient children and their age peers and can impair bone mineralization. There have also been attempts to forestall epiphyseal fusion in boys by giving drugs that inhibit aromatase, the enzyme responsible for converting androgens to estrogens. Therapy should be continued until near-final height is achieved. Criteria for stopping GH treatment include a decision by the patient that he or she is tall enough, a growth rate >1 inch/yr, and a bone age >14 yr in girls and >16 yr in boys.

Some patients develop either primary or central hypothyroidism while under treatment with GH. Similarly, there is a risk of developing adrenal insufficiency. If unrecognized, this can be fatal. Periodic evaluation of thyroid and adrenal function is indicated for all patients treated with GH.

Recombinant IGF-1 is approved for use in the United States. It is given subcutaneously twice a day. The risk of hypoglycemia is reduced by giving the injections concurrently with a meal or snack. In some situations its use is more efficacious than use of GH. These conditions include abnormalities of the GH receptor and STAT5b genes, as well as severe GH deficiency in patients who have developed antibodies to administered GH. Its utility in improving growth rate and adult stature in broader categories of short children is being explored.

The doses of GH used to treat children with classic GH deficiency usually enhance the growth of many non-GH-deficient children as well. Intensive investigation is in progress to determine the full spectrum of short children who may benefit from treatment with GH. The FDA approval for use of GH in idiopathic short stature specifies a height below the 1.2 percentile (~2.25 SD) for age and sex, a predicted height below the 5th percentile, and open epiphyses. Studies of the effect of GH treatment on adult height suggest a median gain of 2-3 inches, depending on dose and duration of treatment.

In children with MPHDI, replacement should also be directed at other hormonal deficiencies. In TSH-deficient patients, thyroid hormone is given in full replacement doses. In ACTH-deficient patients, the optimal dose of hydrocortisone should not exceed 10 mg/m²/24 hr. Increases of 2-3-fold are made to provide stress coverage during illness or in anticipation of surgical procedures. In patients with a deficiency of gonadotropins, gonadal steroids are given when bone age reaches the age at which puberty usually takes place. For infants with micropenis, 1 or 2 three-month courses of monthly intramuscular injections of 25 mg of testosterone cypionate or testosterone enanthate can bring the penis to normal size without an inordinate effect on osseous maturation.

COMPLICATIONS AND ADVERSE EFFECTS OF GH TREATMENT

GH treatment influences glucose homeostasis. Fasting and postprandial insulin levels are characteristically low before treatment, and they normalize during GH replacement. Recent studies indicate that GH
treatment is associated with a 6-fold increase in the risk for type 2 diabetes and no significant increase in the risk for type 1 diabetes.

Concerns have been raised about the safety of GH treatment in children who become deficient after treatment of brain tumors, leukemia, and other neoplasms. Long-term studies show no increase in risk of recurrence of craniopharyngioma, other brain tumors, or leukemia. At least 3 studies indicate an increased risk of second neoplasms in cancer survivors treated with GH. An unconfirmed study documents a 30% increase in mortality among young adults who received GH in childhood. There appears to be a correlation between risk of mortality and GH doses >0.35 mg/kg/wk.

Other reported side effects include pseudotumor cerebri, slipped capital femoral epiphysis, gynecomastia, and worsening of scoliosis, and in adults treated as a child there is an increased risk of hemorrhagic stroke. The risk of later development of Creutzfeldt-Jakob disease was limited to recipients of contaminated lots of extracted pituitary GH. No comparable risks have been seen with recombinant hGH.

Bibliography is available at Expert Consult.
Diabetes insipidus (DI) manifests clinically with polyuria and polydipsia and can result from either vasopressin deficiency (central DI) or vasopressin insensitivity at the level of the kidney (nephrogenic DI). Both central DI and nephrogenic DI can arise from inherited defects of congenital or neonatal onset or can be secondary to a variety of causes (Table 558-1).

**PHYSIOLOGY OF WATER BALANCE**

The control of extracellular tonicity (osmolality) and volume within a narrow range is critical for normal cellular structure and function (see Chapter 55.2). Extracellular fluid tonicity is regulated almost exclusively by water intake and excretion, whereas extracellular volume is regulated by sodium intake and excretion. The control of plasma tonicity and intravascular volume involves a complex integration of endocrine, neural, behavioral, and paracrine systems (Fig. 558-1). Vasopressin, secreted from the posterior pituitary, is the principal regulator of tonicity, with its release largely stimulated by increases in plasma tonicity. Volume homeostasis is largely regulated by the renin–angiotensin–aldosterone system, with contributions from both vasopressin and the natriuretic peptide family.

Vasopressin, a 9-amino-acid peptide, has both antidiuretic and vascular pressor activity and is synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. It is transported to the posterior pituitary via axonal projections, where it is stored awaiting release into the systemic circulation. The half-life of vasopressin in the circulation is 5 min. In addition to responding to osmotic stimuli, vasopressin is secreted in response to significant decreases in intravascular volume and pressure (minimum of 8% decrement) via afferent baroreceptor pathways arising from the aortic arch (carotid sinus) and volume receptor pathways in the cardiac atria and pulmonary veins. Osmotic and hemodynamic stimuli interact synergistically.

The sensation of thirst is regulated by cortical as well as hypothalamic neurons. The thirst threshold is approximately 10 mOsm/kg higher (i.e., 293 mOsm/kg) than the osmotic threshold for vasopressin release. Consequently, under conditions of hyperosmolality, vasopressin is released before thirst is initiated, allowing ingested water to be retained. Chemoreceptors present in the oropharynx rapidly down-regulate vasopressin release following water ingestion.

Vasopressin exerts its principal effect on the kidney via V2 receptors located primarily in the collecting tubule, the thick ascending limb of the loop of Henle, and the periglomerular tubules. The human V2 receptor gene is located on the long arm of the X chromosome (Xq28) at the locus associated with congenital, X-linked, vasopressin-resistant DI. Activation of the V2 receptor results in increases in intracellular cyclic adenosine monophosphate, which leads to the insertion of the aquaporin-2 water channel into the apical (luminal) membrane. This allows water movement along its osmotic gradient into the hypertonic inner medullary interstitium from the tubule lumen and excretion of concentrated urine. In contrast to aquaporin-2,
Atrial natriuretic peptide, initially isolated from cardiac atrial muscle, has a number of important effects on salt and water balance, including stimulation of natriuresis, inhibition of sodium resorption, and inhibition of vasopressin secretion. Atrial natriuretic peptide is expressed in endothelial cells and vascular smooth muscle, where it appears to regulate relaxation of arterial smooth muscle. Atrial natriuretic peptide is also expressed in the brain, along with other natriuretic family members; the physiologic role of these factors has yet to be defined.

**APPRAOCH TO THE PATIENT WITH POLYURIA, POLYDIPSIA, AND HYPERNATREMIA**

The cause of pathologic polyuria or polydipsia (exceeding 2 L/m²/24 hr) may be difficult to establish in children. Infants can present with irritability, failure to thrive, and intermittent fever. Patients with suspected DI should have a careful history taken, which should quantify the child’s daily fluid intake and output and establish the voiding pattern, nocturia, and primary or secondary enuresis. A complete physical examination should establish the patient’s hydration status, and the physician should search for evidence of visual and central nervous system dysfunction, as well as for other pituitary hormone deficiencies.

If pathologic polyuria or polydipsia is present, the following should be obtained: serum for osmolality, sodium, potassium, blood urea nitrogen, creatinine, glucose, and calcium; urine for osmolality, specific gravity, and glucose determination. The diagnosis of DI is established if the serum osmolality is >300 mOsm/kg and the urine osmolality is <300 mOsm/kg. DI is unlikely if the serum osmolality is <270 mOsm/kg or the urine osmolality is >600 mOsm/kg. If the patient’s serum osmolality is <300 mOsm/kg (but >270 mOsm/kg) and pathologic polyuria and polydipsia are present, a water deprivation test is indicated to establish the diagnosis of DI and to differentiate central from nephrogenic causes.

In the inpatient postneurosurgical setting, central DI is likely if hyperosmolality (serum osmolality >300 mOsm/kg) is associated with urine osmolality less than serum osmolality. It is important to distinguish between polyuria resulting from postsurgical central DI and polyuria resulting from the normal diuresis of fluids received intraoperatively. Both cases may be associated with a large volume (>200 mL/m²/hr) of dilute urine, although in patients with DI, the serum osmolality is high in comparison with patients undergoing postoperative diuresis.

**CAUSES OF HYPERNATREMIA**

Hypernatremia is discussed in Chapter 55.3.

**Central Diabetes Insipidus**

Central DI can result from multiple etiologies, including genetic mutations in the vasopressin gene; trauma (accidental or surgical) to vasopressin neurons; congenital malformations of the hypothalamus or pituitary; neoplasms; infiltrative, autoimmune, and infectious diseases affecting vasopressin neurons or fiber tracts; and increased metabolism of vasopressin. In approximately 10% of children with central DI, the etiology is idiopathic. Other pituitary hormone deficiencies may be present (see Chapter 557). Over time, up to 35% of those with idiopathic central DI will develop other hormone deficiencies or have an underlying etiology identified.

Autosomal dominant central DI usually occurs within the 1st 5 yr of life and results from mutations in the vasopressin gene. A number of mutations can cause gene-processing defects in a subset of vasopressin-expressing neurons, which have been postulated to result in endoplasmic reticulum stress and cell death. Wolfram syndrome, which includes DI, diabetes mellitus, optic atrophy, and deafness, also results in vasopressin deficiency. Mutations in 2 genes, which give rise to endoplasmic reticulum proteins, are associated with this condition. Congenital brain abnormalities (see Chapter 591) such as optic nerve hypoplasia syndrome with agenesis of the corpus callosum, the Niikawa-Kuroki syndrome, holoprosencephaly, and familial pituitary hypoplasia with absent stalk may be associated with central DI and defects in thirst perception. Empty sella syndrome, possibly resulting from unrecognized pituitary infarction (see Chapter 557), can be associated with DI in children.

Trauma to the base of the brain and neurosurgical intervention in the region of the hypothalamus or pituitary are common causes of central DI. The triphasic response following surgery refers to an initial phase of transient DI, lasting 12-48 hr, followed by a 2nd phase of syndrome of inappropriate antidiuretic hormone secretion, lasting up to 10 days, which may be followed by permanent DI. The initial phase may be the result of local edema interfering with normal vasopressin secretion; the 2nd phase results from unregulated vasopressin release from dying neurons, whereas in the 3rd phase, permanent DI results if more than 90% of the neurons have been destroyed.

Given the anatomic distribution of vasopressin neurons over a large area within the hypothalamus, tumors that cause DI must either be very large and infiltrative or be strategically located near the base of the hypothalamus, where vasopressin axons converge before their entry into the posterior pituitary. Germinomas and pinealomas typically arise in this region and are among the most common primary brain tumors associated with DI. Germinomas can be very small and undetectable by MRI for several years following the onset of polyuria. Quantitative measurement of α- and β-human chorionic gonadotropin, often secreted by germinomas, should be performed in children with idiopathic or unexplained DI in addition to serial MRI scans. Craniorhynogiasms and optic gliomas can also cause central DI when they are very large, although this is more often a postoperative complication of the treatment for these tumors (see Chapter 497). Hematologic malignancies, such as acute myelocytic leukemia, can cause DI via infiltration of the pituitary stalk and sella.

Langerhans cell histiocytosis (see Chapter 507) and lymphocytic hypophysitis are common types of infiltrative disorders causing central DI, with hypophysitis as the cause in 50% of cases of “idiopathic” central DI. Infections involving the base of the brain (see Chapter 603), including meningitis (meningococcal, cryptococcal, listerial, toxoplasmal), congenital cytomegalovirus infection, and nonspecific inflammatory diseases of the brain may give rise to central DI that is often transient. Drugs associated with the inhibition of vasopressin release include ethanol, phenytoin, opiate antagonists, halothane, and α-adrenergic agents.

**Nephrogenic Diabetes Insipidus**

Nephrogenic (vasopressin-insensitive) DI (NDI) can result from genetic or acquired causes. Genetic causes are less common but more severe than acquired forms of NDI. The polyuria and polydipsia associated with NDI usually occur within the 1st several wk of life, but may only become apparent after weaning or with longer periods of nighttime sleep. Many infants initially present with fever, vomiting, and dehydration. Failure to thrive may be secondary to the ingestion of large amounts of water, resulting in caloric malnutrition. Long-standing ingestion and excretion of large volumes of water can lead to nonobstructive hydropnephrosis, hydrourter, and megablabadder.

Congenital X-linked NDI results from inactivating mutations of the vasopressin V2 receptor. Congenital autosomal recessive NDI results from defects in the aquaporin-2 gene. An autosomal dominant form of NDI is associated with processing mutations of the aquaporin-2 gene.

Acquired NDI can result from hypercalcemia or hypokalemia and is associated with lithium, democlocycline, foscarnet, clozapine, amphotericin, methicillin, and rifampin. Impaired renal concentrating ability can also be seen with ureteral obstruction, chronic renal failure, polycystic kidney disease, medullary cystic disease, Sjögren syndrome, and sickle cell disease. Decreased protein or sodium intake or excessive water intake, as in primary polydipsia, can lead to diminished toxicity of the renal medullary interstitium and NDI.
TREATMENT OF CENTRAL DIABETES INSIPIDUS

Fluid Therapy

With an intact thirst mechanism and free access to oral fluids, a person with complete DI can maintain plasma osmolality and sodium in the high normal range, although at great inconvenience. Neonates and young infants are often best treated solely with fluid therapy, given their requirement for large volumes (3 L/m²/24 hr) of nutritive fluid. The use of vasopressin analogs in patients with obligate high fluid intake is difficult given the risk of life-threatening hyponatremia. Although not FDA approved, the use of diluted parenteral and lyophilized long-acting vasopressin analog DDAVP (desmopressin) has been successfully administered to infants with central DI both subcutaneously and orally without causing severe hyponatremia.

Vasopressin Analogs

Treatment of central DI in older children is best accomplished with the use of DDAVP. DDAVP is available in an intranasal preparation (onset 5-10 min) and as tablets (onset 15-30 min). The intranasal preparation of DDAVP (10 µg/0.1 mL) can be administered by rhinal tube (allowing dose titration) or by nasal spray. Use of DDAVP oral tablets requires at least a 10-fold increase in the dosage compared with the intranasal preparation. Oral dosages of 25-300 µg every 8-12 hr are safe and effective in children. The appropriate dosage and route of administration is determined empirically based on the desired length of antidiuresis and patient preference. The use of DDAVP nasal spray (10 µg/0.1 mL) for the treatment of primary enuresis in older children should be regarded as a temporizing measure, given it does not affect the underlying condition, and should be used with great caution given the risk of hyponatremia if water intake exceeds the capacity for renal clearance. To prevent water intoxication, patients should have at least 1 hr of urinary breakthrough between doses each day and be advised to drink in response to thirst sensation.

Aqueous Vasopressin

Central DI of acute onset following neurosurgery is best managed with continuous administration of synthetic aqueous vasopressin (Pitressin). Under most circumstances, total fluid intake must be limited to 1 L/m²/24 hr during antidiuresis. A typical dosage for intravenous vasopressin therapy is 1.5 mU/kg/hr, which results in a blood vasopressin concentration of approximately 10 pg/mL. On occasion, following hypothalamic (but not transsphenoidal) surgery, higher initial concentrations of vasopressin may be required to treat acute DI, which has been attributed to the release of a vasopressin inhibitory substance. Vasopressin concentrations >1,000 pg/mL should be avoided because they can cause cutaneous necrosis, rhabdomyolysis, cardiac rhythm disturbances, and hypertension. Postneurosurgical patients treated with vasopressin infusion should be switched from intravenous to oral fluids as soon as possible to allow thirst sensation, if intact, to help regulate osmolality.

TREATMENT OF NEPHROGENIC DIABETES INSIPIDUS

The treatment of acquired NDI focuses on eliminating, if possible, the underlying disorder, such as offending drugs, hypercalcemia, hypokalemia, or ureteral obstruction. Congenital nephrogenic DI is often difficult to treat. The main goals are to ensure the intake of adequate calories for growth and to avoid severe dehydration. Foods with the highest ratio of caloric content to osmotic load (Na <1 mmol/kg/24 hr) should be ingested to maximize growth and to minimize the urine volume required to excrete the solute load. Even with the early institution of therapy, however, growth failure and developmental disabilities are common.

Pharmacologic approaches to the treatment of NDI include the use of thiazide diuretics and are intended to decrease the overall urine output. Thiazides appear to induce a state of mild volume depletion by enhancing sodium excretion at the expense of water and by causing a decrease in the glomerular filtration rate, which results in proximal tubular sodium and water reabsorption. Indomethacin and amiloride may be used in combination with thiazides to further reduce polyuria. High-dose DDAVP therapy, in combination with indomethacin, has been used in some subjects with NDI. This treatment could prove useful in patients with genetic defects in the V2 receptor associated with a reduced binding affinity for vasopressin.

Bibliography is available at Expert Consult.
Bibliography
Hyponatremia (serum sodium <130 mEq/L) in children is usually associated with severe systemic disorders and is most often a result of intravascular volume depletion, excessive salt loss, or hypotonic fluid overload, especially in infants (see Chapter 55).

The initial approach to the patient with hyponatremia begins with determination of the volume status. A careful review of the patient's history, physical examination (including changes in weight), and vital signs helps determine whether the patient is hypovolemic or hypervolemic. Supportive evidence includes laboratory data such as serum electrolytes, blood urea nitrogen, creatinine, uric acid, urine sodium, specific gravity, and osmolality (see Chapter 55; Tables 559-1 and 559-2).

NSIAD, nephrogenic syndrome of inappropriate antidiuresis; SIADH, syndrome of inappropriate antidiuretic hormone secretion.
CAUSES OF HYponatREMIA
Syndrome of Inappropriate Antidiuretic Hormone Secretion
Syndrome of inappropriate antidiuretic hormone secretion (SIADH) is characterized by hyponatremia, an inappropriately concentrated urine (>100 mOsm/kg), normal or slightly elevated plasma volume, normal-to-high urine sodium, and low serum uric acid. SIADH is uncommon in children, and most cases result from excessive administration of vasopressin in the treatment of central diabetes insipidus. It can also occur with encephalitis, brain tumors, head trauma, psychiatric disease, prolonged nausea, pneumonia, tuberculous meningitis, and AIDS and in the postictal phase following generalized seizures. SIADH is the cause of the hyponatremic second phase of the triphasic response seen after hypothalamic–pituitary surgery (see Chapter 558). It is found in up to 35% of patients 1 wk after surgery and can result from retrograde neuronal degeneration with cell death and vasopressin release. Common drugs that have been shown to increase vasopressin secretion or mimic vasopressin action, resulting in hyponatremia, include oxcarbazepine, carbamazepine, chlorpropamide, vinblastine, vincristine, and tricyclic antidepressants.

Nephrogenic Syndrome of Inappropriate Antidiuresis
Gain-of-function mutations in the V2 vasopressin receptor gene have been described in male infants presenting with an SIADH-like clinical picture with undetectable vasopressin levels. Activating mutations in the aquaporin-2 gene might also give rise to the same syndrome but have not yet been described.

Systemic Dehydration
The initial manifestation of systemic dehydration is often hyponatremia and hyperosmolality, which subsequently lead to the activation of vasopressin secretion and a decrease in water excretion. As dehydration progresses, hypovolemia and/or hypotension become a major stimulus for vasopressin release, further decreasing free water clearance. Excessive free water intake with ongoing salt loss can also produce hyponatremia. Urinary sodium excretion is low (usually <10 mEq/L) owing to a low glomerular filtration rate and concomitant activation of the renin–angiotensin–aldosterone system, unless primary renal disease or diuretic therapy is present.

Primary Salt Loss
Hyponatremia can result from the primary loss of sodium chloride as seen in specific disorders of the kidney (congenital polycystic kidney disease, acute interstitial nephritis, chronic renal failure), gastrointestinal tract (gastroenteritis), and sweat glands (cystic fibrosis). The hyponatremia is not solely caused by the salt loss, because the latter also causes hypovolemia, leading to an increase in vasopressin. Mineralocorticoid deficiency (hypoaldosteronism), pseudohypoaldosteronism (genetic or sometimes seen in children with urinary tract obstruction or infection), and diuretics can also result in loss of sodium chloride. Hypoaldosterone states are associated with salt wasting, hypovolemia, hyponatremia, hyperkalemia, and failure to thrive (Table 559-3).

Decreased Effective Plasma Volume
Hyponatremia can result from decreased effective plasma volume, as found in congestive heart failure, cirrhosis, nephrotic syndrome, positive pressure mechanical ventilation, severe burns, bronchopulmonary dysplasia in neonates, cystic fibrosis with obstruction, and severe asthma. The resulting decrease in cardiac output leads to reduced water and salt excretion, as with systemic dehydration, and an increase in vasopressin secretion. In patients with impaired cardiac output and elevated atrial volume (congestive heart failure, lung disease), atrial natriuretic peptide concentrations are elevated further, leading to hyponatremia by promoting natriuresis. However, owing to the marked elevation of aldosterone in these patients, their urine sodium remains low (<20 mEq/L) despite this. Unlike dehydrated patients, these patients also have excess total body sodium from activation of the renin–angiotensin–aldosterone system and can demonstrate peripheral edema as well.

Primary Polydipsia (Increased Water Ingestion)
In patients with normal renal function, the kidney can excrete dilute urine with an osmolality as low as 50 mOsm/kg. To excrete a daily solute load of 500 mOsm/m^2, the kidney must produce 10 L/m^2 of urine per day. Therefore, to avoid hyponatremia, the maximum amount of water a person with normal renal function can consume is 10 L/m^2. Neonates, however, cannot dilute their urine to this degree, putting them at risk for water intoxication if water intake exceeds 4 L/m^2/day (approximately 60 mL/hr in a newborn). Many infants develop transient but symptomatic hyponatremic seizures after being fed pure water without electrolytes rather than breast milk or formula.

Decreased Free Water Clearance
Hyponatremia as a consequence of decreased renal free water clearance, even in the absence of an increase in vasopressin secretion, can result from adrenal insufficiency or thyroid deficiency or can be related to a direct effect of drugs on the kidney. Both mineralocorticoids and glucocorticoids are required for normal free water clearance in a vasopressin-independent manner. In patients with unexplained hyponatremia, adrenal and thyroid insufficiency should be considered. In addition, patients with coexisting adrenal failure and diabetes insipidus might have no symptoms of the latter until glucocorticoid therapy unmasks the need for vasopressin replacement. Certain drugs can inhibit renal water excretion through direct effects on the nephron, thus causing hyponatremia; these drugs include high-dose cyclophosphamide, vinblastine, cisplatinum, carbamazepine, and oxcarbazepine.

Cerebral Salt Wasting
Cerebral salt wasting appears to be the result of hypersecretion of atrial natriuretic peptide and is seen primarily with central nervous system disorders including brain tumors, head trauma, hydrocephalus, neurorsurgery, cerebrovascular accidents, and brain death. Hyponatremia is accompanied by elevated urinary sodium excretion (often >150 mEq/L), excessive urine output, hypovolemia, normal or high uric acid, suppressed vasopressin, and elevated atrial natriuretic
peptide concentrations (>20 pmol/L). Thus, it is distinguished from SIADH, in which normal or decreased urine output, euovolemia, only modestly elevated urine sodium concentration, and an elevated vasopressin level occur. The distinction between cerebral salt wasting and SIADH is important because the treatment of the 2 disorders differs markedly. However, its existence has been questioned, because few patients with the suspected syndrome have documented hypovolemia and thus might truly have SIADH.

**Runners’ Hyponatremia**

Excess fluid ingestion during long-distance running (e.g., marathon running) can result in severe hyponatremia from hypovolemia-induced activation of arginine vasopressin secretion coupled with excessive water ingestion and is correlated with weight gain, long racing time, and extremes of body mass index.

**Pseudohyponatremia and Other Causes of Hyponatremia**

Pseudohyponatremia can result from hypertriglyceridemia (see Chapter 55). Elevated lipid levels result in a relative decrease in serum water content. As electrolytes are dissolved in the aqueous phase of the serum, they appear low when expressed as a fraction of the total serum volume. As a fraction of serum water, however, electrolyte content is normal. Modern laboratory methods that measure sodium concentration directly, independent of sample volume, do not cause this anomaly. Facitious hyponatremia can result from obtaining a blood sample proximal to the site of intravenous hypotonic fluid infusion.

Hyponatremia is also associated with hyperglycemia, which causes the influx of water into the intravascular space. Serum sodium decreases by 1.6 mEq/L for every 100 mg/dL increment in blood glucose >100 mg/dL. Glucose is not ordinarily an osmotically active agent and does not stimulate vasopressin release, probably because it can equilibrate freely across plasma membranes. In the presence of insulin deficiency and hyperglycemia, however, glucose acts as an osmotic agent, presumably because its normal intracellular access to osmosensor sites is prevented. Under these circumstances, an osmotic gradient exists, stimulating vasopressin release.

**TREATMENT**

Patients with systemic dehydration and hypovolemia should be rehydrated with salt-containing fluids such as normal saline or lactated Ringer solution. Because of activation of the renin–angiotensin–aldosterone system, the administered sodium is avidly conserved, and water diuresis quickly ensues as volume is restored and vasopressin concentrations decrease. Under these conditions, caution must be taken to prevent a too-rapid correction of hyponatremia, which can

result in central pontine myelinolysis characterized by discrete regions of axonal demyelination and the potential for irreversible brain damage.

Hyponatremia from a decrease in effective plasma volume caused by cardiac, hepatic, renal, or pulmonary dysfunction is more difficult to reverse. The most effective therapy is the least easily achieved: treatment of the underlying systemic disorder. For example, patients weaned from positive pressure ventilation undergo a prompt water diuresis and resolution of hyponatremia as cardiac output is restored and vasopressin concentrations decrease. Vaptans represent a new class of small-molecule arginine vasopressin V2 receptor antagonists (aquaretics) useful for the treatment of hypervolemic hyponatremia associated with severe congestive heart failure and chronic liver failure. Although these agents successfully increase plasma sodium, they also lead to increased thirst and plasma vasopressin levels, which can limit their effectiveness.

Patients with hyponatremia from primary salt loss require supplementation with sodium chloride and fluids. Initially, intravenous replacement of urine volume with fluid containing sodium chloride, 150–450 mEq/L depending on the degree of salt loss, may be necessary; oral salt supplementation may be required subsequently. This treatment contrasts with that of SIADH, in which water restriction without sodium supplementation is the mainstay.

Emergency Treatment of Hyponatremia
The development of acute hyponatremia (onset <12 hr) or a serum sodium concentration <120 mEq/L may be associated with lethargy, psychosis, coma, or generalized seizures, especially in younger children. Acute hyponatremia can cause cell swelling and lead to neuronal dysfunction or to cerebral herniation. The emergency treatment of cerebral dysfunction resulting from acute hyponatremia includes water restriction and can require rapid correction with hypertonic 3% sodium chloride. If hypertonic saline treatment is undertaken, the serum sodium should be raised only high enough to cause an improvement in mental status, and in no case faster than 0.5 mEq/L/hr or 12 mEq/L/24 hr.

Treatment of Syndrome of Inappropriate Antidiuretic Hormone
Chronic SIADH is best treated by oral fluid restriction. With full antidiuresis (urine osmolality of 1,000 mOsm/kg), a normal daily obligate renal solute load of 500 mOsm/m² would be excreted in 500 mL/m² water. This, plus a daily nonrenal water loss of 500 mL/m², would require that oral fluid intake be limited to 1,000 mL/m²/24 hr to avoid hyponatremia. In young children, this degree of fluid restriction might not provide adequate calories for growth. In this situation, the creation of nephrogenic diabetes insipidus using demeclocycline therapy may be indicated to allow sufficient fluid intake for normal growth. Urea has also been safely used to induce an osmotic diuresis in infants and children.

Treatment of Cerebral Salt Wasting
